This report is based on research conducted by the Pacific Northwest Evidence-based Practice Center (EPC) under contract to the Agency for Healthcare Research and Quality (AHRQ), Rockville, MD (Contract No. HHSA-290-2015-00009-I, Task Order No. 7). The findings and conclusions in this document are those of the authors, who are responsible for its contents, and do not necessarily represent the views of AHRQ. Therefore, no statement in this report should be construed as an official position of AHRQ or of the U.S. Department of Health and Human Services.

The information in this report is intended to help health care decisionmakers—patients and clinicians, health system leaders, and policymakers, among others—make well-informed decisions and thereby improve the quality of health care services. This report is not intended to be a substitute for the application of clinical judgment. Anyone who makes decisions concerning the provision of clinical care should consider this report in the same way as any medical reference and in conjunction with all other pertinent information (i.e., in the context of available resources and circumstances presented by individual patients).

The final report may be used, in whole or in part, as the basis for development of clinical practice guidelines and other quality enhancement tools, or as a basis for reimbursement and coverage policies. AHRQ or U.S. Department of Health and Human Services endorsement of such derivative products may not be stated or implied.

None of the investigators have any affiliations or financial involvement that conflicts with the material presented in this report.

Acknowledgments

The authors gratefully acknowledge the following individuals for their contributions to this project: Dr. Iris Mabry-Hernandez, Medical Officer at AHRQ; and current and former members of the U.S. Preventive Services Task Force who contributed to topic deliberations.
Structured Abstract

Background: In 2006, the U.S. Preventive Services Task Force recommended against routine screening for elevated blood lead levels in asymptomatic pregnant women (D recommendation).

Objective: To update a prior systematic review on screening for elevated blood lead levels in pregnancy for the U.S. Preventive Services Task Force.

Data Sources: Cochrane Central Register of Controlled Trials (to March 2017) and Cochrane Database of Systematic Reviews (to June 2018), MEDLINE (1946 to June 2018), and reference lists.

Study Selection: English-language trials and observational studies of screening effectiveness, test accuracy, benefits and harms of screening and interventions.

Data Extraction: One investigator abstracted details about study design, patient population, setting, screening method, followup, and results. Two investigators independently applied prespecified criteria to rate study quality using methods developed by the USPSTF. Discrepancies were resolved through consensus.

Results: No studies directly evaluated clinical benefits and harms of screening pregnant women for elevated lead levels versus no screening, or how effectiveness of screening varies according to the gestational age at which screening is performed. One fair-quality study evaluated the diagnostic accuracy of using a version of the CDC screening questionnaire for lead exposure in children, modified for identifying pregnant women with elevated lead levels. The study used four out of five of the questions from the CDC questionnaire and demonstrated a sensitivity of 75.7% and specificity of 46.2%. The most predictive single item was living in a home built before 1960. One fair-quality RCT from Mexico found that calcium supplementation in healthy pregnant women (mean baseline lead levels ~ 4 µg/dL) was associated with a reduction in serum lead levels compared with placebo (difference 11%, p=0.004). No studies reported health outcomes or harms associated with interventions to reduce blood levels in asymptomatic pregnant women.

Limitations: Limited to English-language articles; quality and applicability of studies were limited due to flawed study design, poor reporting of statistical outcomes, and loss to followup. Two studies addressed the key questions, with no evidence on effects of screening or interventions for elevated lead levels in pregnant women on health outcomes.

Conclusions: Evidence on the benefits and harms of screening pregnant women for elevated blood lead levels is extremely limited, with no evidence on effects of screening or interventions for lowering elevated blood lead levels in pregnant women on health outcomes.

Chapter 1. Introduction and Background

Purpose

This report will be used by the U.S. Preventive Services Task Force (USPSTF) to update its 2006 recommendation on screening for elevated lead levels in pregnancy. This update focuses on studies published since the prior USPSTF systematic review of this topic and may include studies also included in the prior review.

In 2006, the USPSTF recommended against routine screening for elevated blood lead levels (BLLs) in asymptomatic pregnant women (D recommendation). The USPSTF found no studies that examined the effectiveness or harms of screening or interventions among pregnant women but did discuss a variety of potential harms similar to those with children. Given the low prevalence of elevated blood lead levels in asymptomatic pregnant women, the small amount of potential benefit was not thought to outweigh the potential harms of screening and intervention in this group.

Condition Background

Condition Definition

For this report elevated blood lead level (BLL), or blood lead concentration, was defined according to the Centers for Disease Control and Prevention’s (CDC’s) reference level of 5 micrograms per deciliter (µg/dL). Although no safe level of lead exposure has been established, this is the level at which further clinical monitoring or treatment is recommended for pregnant women. This reference range value was based on the 98th percentile of the National Health and Nutrition Examination Survey’s (NHANES’s) blood lead distribution in women of childbearing age.

Prevalence and Burden of Disease/Illness

Lead is known to cause a number of adverse health effects, primarily affecting the central nervous, hematopoietic, hepatic, and renal systems. Manifestations are variable. However, there is a general correlation between higher BLLs and the presence of symptoms. Acute toxicity resulting from intense lead exposure over a short duration is very uncommon and primarily associated with occupational exposure. Clinical symptoms of acute lead exposure include muscle pain, fatigue, abdominal pain, headache, vomiting, seizures, and coma. Adults with lower level, chronic, or recurrent exposures may be asymptomatic or present with vague nonspecific symptoms (e.g., myalgia, fatigue, difficulty concentrating, and insomnia).

Many potential health effects of lead exposure are irreversible. Compared with other organ systems, the nervous system appears to be the most sensitive and chief target for lead-induced toxicity. More severe manifestations occur at very high exposures and include delirium, lack of
coordination, convulsions, paralysis, coma, and ataxia. Lead exposure can lead to anemia by directly affecting the synthesis of hemoglobin (by inhibiting various key enzymes involved in the heme synthesis pathway) and by reducing the life span of circulating erythrocytes by increasing the fragility of cell membranes.

Pregnant women exposed to lead are at an increased risk of adverse perinatal outcomes as well as non-pregnancy-related morbidity. Among adults in general, analyses of NHANES data (1988 to 1994) indicate that BLLs >10 µg/dL are associated with an increased risk of death from all causes (risk ratio [RR] 1.59; 95% CI, 1.28 to 1.98), cardiovascular disease (RR 1.55; 95% CI, 1.16 to 2.07), and cancer (RR 1.69; 95% CI, 1.14 to 2.52). Exposure in adults can additionally lead to increased blood pressure and the incidence of hypertension, reproductive problems, and decreased kidney function.

The International Agency for Research on Cancer lists lead as a probable carcinogen and the U.S Report on carcinogens also lists lead and lead compounds as “reasonably anticipated to be a human carcinogen.” Lead exposure during pregnancy can result in spontaneous abortion, reduced fetal growth, premature birth, and cognitive deficiencies in the child. As with young children, lead exposure during the critical initial neurological development of a fetus may be particularly harmful. Pregnant women and nursing mothers with high BLLs may experience elevations in both systolic and diastolic blood pressure.

Public health efforts to reduce exposure to lead in the United States (e.g., removal of lead from household paints and gasoline) are considered major successes. Although it is difficult to measure changes in morbidity attributable to lead exposure, the percentages of adults with elevated BLLs have declined significantly over the past few decades.

Based on NHANES data, the percentage of adults with BLLs of 10 µg/dL or higher declined from 3.3 percent in 1988 to 1994 to 0.7 percent in 1999 to 2002 (p <0.001). In 1999 to 2002, the multivariable-adjusted odds ratio of having a BLL of 10 µg/dL or higher was 2.91 (95% confidence interval [CI], 1.74 to 4.84) and 3.26 (95% CI, 1.83 to 5.81) for non-Hispanic blacks and Mexican-Americans, respectively, compared with non-Hispanic whites. Among women of childbearing age, an estimated 1 percent have BLLs above 5 µg/dL. In one analysis of pregnant women, the age-adjusted prevalence of elevated BLLs was <0.5 percent, and exact prevalence could not be reliably detected.

**Etiology and Natural History**

Lead is a heavy metal that occurs naturally in the environment. Unique properties of lead (e.g., high malleability, low melting point, and resistance to corrosion) have resulted in its widespread use in various industries. Lead has become widely distributed and mobilized in the environment, resulting in increasing human exposure and uptake over time.

Common sources of lead exposure include lead-based paint, contaminated soil (e.g., by exterior lead-based paint or gasoline), lead-contaminated water (e.g., by lead plumbing), and dust contaminated by chipping or chalking of lead-based paint and tracked-in soil. In the United States, leaded gasoline began to be phased out in 1973 and was banned by 1996. From 1980 to 2014, exposure to lead fumes from leaded gasoline decreased by 98 percent. Lead-based paints were banned for use in housing in 1978. All houses built before 1978 are likely to contain some Lead Screening in Pregnant Women

Pacific Northwest EPC
lead-based paint that ultimately deteriorates and causes a problem.\textsuperscript{15} Although lead was restricted in plumbing material in 1986, older homes and neighborhoods may still contain lead service lines, lead connections, or other lead-based plumbing materials.\textsuperscript{17} The release of lead from lead-based plumbing materials into drinking water is variable and influenced by factors such as water softness, temperature, and acidity.\textsuperscript{18} Flint, Michigan provides an example in which lead contamination of drinking water was increased by and may be impacted by changes in water sources and changes in water treatment, including the use of disinfectants.\textsuperscript{19}

Like young children, adults may be exposed to lead-based paints and other household exposures. Adults may also be at risk of occupational lead exposure, exposure via hobbies (e.g., lead-glazed pottery), and ingestion of some lead-containing complementary and alternative treatments (e.g., Ayurvedic herbal medicine products). One survey of reproductive-age women in New York with elevated BLLs (10 to 25 µg/dL) found that 46 percent of exposures were occupational, 24 percent were due to home renovations, and 30 percent were unknown.\textsuperscript{20} Among women with occupational exposures to lead fumes or dust, the most common occupational exposures were precision production (e.g., work involving soldering or the production of lead-containing materials), craft and repair operations, and operators, fabricators, and laborers. Specific recommendations exist for medical surveillance of pregnant women with occupational exposure to lead.\textsuperscript{21}

Once exposed to lead, nutritional factors in both children and adults are known to affect lead absorption and toxicity. Iron- or calcium-deficient diets may lead to more efficient absorption of lead in children and adults.\textsuperscript{22} Interactions between micronutrients and exposure to lead are also important in pregnancy. Studies suggest that maternal calcium consumption may affect bone resorption based on the toxicokinetics of lead during different stages of pregnancy.\textsuperscript{23} During pregnancy, increased mobilization of lead may occur from bone stores that provide for fetal developmental needs.\textsuperscript{24} Once absorbed, lead is then distributed to the blood, soft tissues, and bone. In blood, 99 percent of lead is bound to the erythrocyte, and the remaining 1 percent is free in the plasma to exchange with soft tissues (kidney, brain, liver, bone marrow). Over 90 percent of lead in the body is stored in bone, and this might be mobilized in periods of high turnover such as pregnancy and lactation.\textsuperscript{3}

During pregnancy, BLLs have been found to follow a U-shaped curve with a nadir between 12 and 20 weeks. The rate at which BLLs rise in late pregnancy varies by age (higher among older women) and is associated with calcium intake (lower in women taking calcium supplements).\textsuperscript{24-26} After delivery, breastfeeding women experience a rise in lead levels that is attributed to increased lead absorption and increased lead mobilization from deeper storage (e.g., bone).\textsuperscript{27}

**Risk Factors**

Risk factors for lead exposure include: socioeconomic disadvantage; living in an area with lead industry; renovation or deterioration of older lead-painted houses; and previously living in developing countries where leaded gasoline is still used.\textsuperscript{15,28} Socioeconomic factors, such as lower family income, older age of housing, and poorer nutritional status are also associated with exposure to lead.
In a New York study of low-income pregnant women, foreign-born women were 8 times more likely to have elevated BLLs compared to women born in the U.S.\(^2\) The American College of Obstetricians and Gynecologists (ACOG) and CDC also list the following as risk factors for lead exposure in pregnant women: living near a point source of lead; working with lead or living with someone who does; using lead-glazed ceramic pottery; eating nonfood substances (e.g., pica); using complementary and alternative therapies; using imported cosmetics; engaging in high-risk hobbies; renovating old homes without lead hazards in place; consuming lead-contaminated drinking water; having a previous history of lead exposure; and living with someone diagnosed with elevated lead levels.\(^3,\!^30\)

Specific risk factors may vary in different communities. For example, exposures that occur through local water sources, lead pipes, as well as culturally linked sources such as folk remedies, imported food and candy, and traditional pottery used for cooking,\(^31,\!^32\) may influence lead exposure on the local level. The CDC recommends that state or local health departments provide information to clinicians on community-specific risk factors that can be used to determine the need for screening in pregnant women.\(^3\) The CDC also recommends developing validated questionnaires at the community level since risk factors may vary significantly between communities.

### Rationale for Screening/Screening Strategies

Current clinical guidelines and policies emphasize primary prevention of lead exposure. The rationale for screening pregnant women is to identify and reduce sources of lead exposure to reduce the risk of pregnancy complications and decrease the risk of lead exposure to the developing fetus and infants. Potential benefits for the pregnant women includes reduction of perinatal complications and prevention of general complications associated with adult lead exposure. As the prevalence of elevated BLLs has declined, there has been a move from universal to targeted screening that incorporates primary prevention education.\(^33\) Although several questionnaires have been developed to identify children at higher risk of lead exposure, none have been developed specifically for pregnant women. Venous sampling is the recommended screening strategy for pregnant women when lead exposure is suspected.\(^3,\!^30\)

### Interventions/Treatment

The management of elevated BLLs in pregnant women varies depending on the confirmed BLL and other factors. Types of interventions include education and environmental strategies, nutritional interventions, and chelation therapy. Identifying the source of lead exposure is a key to preventing ongoing or repeated exposure and remains the mainstay of treatment for lead exposure.

#### Educational and Environmental Interventions

Educational interventions address awareness of lead exposure pathways, hygiene, and household dust control measures to prevent ingestion of dust and soil. Environmental and household interventions include specialized cleaning, repairs, maintenance, soil abatement (e.g., removal
and replacement), painting, and temporary containment of lead hazards. For pregnant women, additional education includes advice on strategies to decrease exposure to children who are breastfeeding. The CDC suggests that breastfeeding be discouraged in women with BLLs greater than or equal to 40 µg/dL, while the 2012 policy statement from the AAP on breastfeeding does not include a recommendation to discourage breastfeeding for women with BLLs greater than or equal to 40 µg/dL. Current guidelines state that women with levels of 5 to 39 µg/dL may breastfeed, but infant BLLs should be measured, and breastfeeding should be discontinued if infant BLLs rise above 5 µg/dL.

**Nutritional Interventions**

The role of nutritional supplementation in reducing BLLs among pregnant women with elevated levels is unclear. Calcium, dietary iron, and other supplements are thought to decrease the intestinal absorption of lead. For lead, this theory is supported by epidemiologic studies that demonstrate an increased prevalence of iron deficiency among children with lead poisoning. However, the association is inconsistent and evidence in iron-replete children is lacking. Nonetheless, calcium and vitamin C supplementation is often recommended for women with elevated BLLs.

**Chelation Therapy**

In adults, chelation therapy may more rapidly decrease BLLs and relieve acute lead symptoms. Initiation of chelation is recommended for individuals with BLLs greater than 100 µg/dL and should also be considered for levels between 80 and 100 µg/dL in asymptomatic individuals and for symptomatic patients with BLLs between 50 and 80 µg/dL. 2,3-dimercaptosuccinic acid, succimer (DMSA) and calcium disodium ethylenediaminetetraacetate (CaEDTA) are commonly used chelating agents. Because treatment with CaEDTA is associated with significant adverse effects it must be administered in a hospital setting. The risks and benefits of chelation therapy have not been fully characterized among pregnant women. There are eight case reports of successful use of chelation in pregnant women, all with BLL >45 µg/dL. The CDC recommends considering the use of chelation when BLLs are above 45 µg/dL. CaEDTA is considered pregnancy category B and DMSA is considered category C. Pregnant women undergoing chelation therapy should be managed by a physician who is experienced with lead intoxication during pregnancy.

**Current Clinical Practice/Recommendations of Other Groups**

**Current Clinical Practice**

There are no available data about the prevalence of providers who screen pregnant women for elevated BLLs. The states of Minnesota and New York recommend routine risk factor assessment for lead exposure as do ACOG and the CDC. The CDC recommends targeted screening for elevated lead levels through venous sampling based on risk factors for lead exposure in individual communities.

The accuracy of screening questionnaires for predicting elevated BLLs in pregnant women is
uncertain. No validated questionnaire exists for identifying pregnant women at high risk of lead exposure. The state of Minnesota\textsuperscript{39} provides a 10-question risk assessment tool, and the state of New York provides a 5-question risk assessment tool.\textsuperscript{3} In both screening programs, BLL testing is recommended if a woman answers yes to one or more questions. However, neither of these tools has been validated in pregnant populations. Venous blood sampling is the recommended screening method for maternal blood lead testing.\textsuperscript{3,30}

**Recommendations of Other Groups**

Table 1 summarizes current screening recommendations from other groups. At the time of the previous Task Force recommendation,\textsuperscript{41} no other groups had issued guidance about screening pregnant women for elevated BLLs. Since 2006, both CDC and ACOG published recommendations stating that all pregnant women with risk factors for lead exposure should be screened for elevated BLLs using venous sampling and managed appropriately.\textsuperscript{3,30}
Chapter 2. Methods

Key Questions and Analytic Framework

This systematic review followed a standard protocol consistent with USPSTF procedures. The scope and Key Questions for this report were developed by EPC investigators in collaboration with the USPSTF and AHRQ, and informed by evidence gaps identified from the prior review. In addition, three contextual questions were requested by the USPSTF. Contextual questions address topics important to the USPSTF recommendations, but are reviewed by summarizing evidence from key informative studies rather than by using systematic review methodology. Key Questions and contextual questions are listed below. Investigators created an analytic framework incorporating the Key Questions and outlining the patient populations, interventions, outcomes, and potential adverse effects (Figure 1). A research plan was externally reviewed and modified prior to finalization.

Key Questions

1a. Is there direct evidence that screening for elevated blood lead levels in asymptomatic pregnant women improves health outcomes (i.e., reduced cognitive problems in offspring, adverse perinatal outcomes, and adverse maternal outcomes)?
1b. Does the effectiveness of screening in asymptomatic pregnant women vary by gestational age?
2. What is the accuracy of questionnaires or clinical prediction tools that identify pregnant women who have elevated blood lead levels?
3. What are the harms of screening for elevated blood lead levels (with or without screening questionnaires) in asymptomatic pregnant women?
4. Do counseling and nutritional interventions, residential lead hazard control techniques, or chelation therapy reduce blood lead levels and rates of gestational hypertension in asymptomatic pregnant women with elevated blood lead levels?
5. Do counseling and nutritional interventions, residential lead hazard control techniques, or chelation therapy improve health outcomes in asymptomatic pregnant women with elevated blood lead levels?
6. What are the harms of interventions in asymptomatic pregnant women with elevated blood lead levels?

Contextual Questions

1. What is the reliability of venous blood lead testing at various lead levels in pregnant women?
2. What is the association between reduced blood lead levels and improved health outcomes in asymptomatic pregnant women with elevated blood lead levels?
3. Are there valid risk prediction tools available that identify communities at highest risk for lead exposure that could be used in primary care practices to target screening efforts in pregnant women?
Key Question 1a focused on direct evidence of the effectiveness of screening for elevated BLLs for improving future health outcomes (i.e., reduced cognitive problems in offspring, reduced adverse perinatal outcomes and reduced adverse maternal outcomes) compared with not screening. Key Question 1b evaluated the effectiveness of screening by gestational age. Because such direct evidence may be limited, the remainder of the analytic framework (Key Questions 2 through 6) evaluates the chain of indirect evidence needed to link screening with improved health outcomes. Links in the chain of indirect evidence include the accuracy of screening for identifying pregnant women with elevated blood lead levels, the effectiveness of interventions for treating identified elevated blood lead levels and reducing the incidence of complications, the association between improvements in intermediate outcomes and clinical health outcomes, and harms (including infant harms) associated with screening and treatments. Implicit in the indirect chain of evidence is that, to understand benefits and harms of screening, it is necessary but not sufficient to show that pregnant women with elevated BLLs can be identified. It is also necessary to show that there are effective treatments for those identified with elevated BLLs.

A separate report covers screening for elevated blood lead levels in children.

**Search Strategies**

We searched the Cochrane Central Register of Controlled Trials (through March, 2017) and Cochrane Database of Systematic Reviews (through April, 2017), and Ovid MEDLINE (1946 through March, 2017) for relevant studies and systematic reviews. Search strategies are available in Appendix A1. We also reviewed the reference lists of relevant review articles and all studies meeting our inclusion criteria. We updated all searches through June, 2018.

**Study Selection**

Two reviewers independently evaluated each study to determine its inclusion eligibility based on predetermined inclusion and exclusion criteria developed for each Key Question (Appendix A2). The target population was asymptomatic pregnant women. Included testing approaches were studies of screening questionnaires. The comparison for KQ1 was screening vs. no screening; for KQ2a questionnaire against reference standard for elevated blood lead level (i.e., venous lead level). We included intermediate outcomes (i.e., blood lead levels) and for clinical outcomes included gestational hypertension, cognitive outcomes in offspring, perinatal and maternal outcomes. Other outcomes were statistical markers of diagnostic accuracy, harms of testing (e.g., anxiety, distress, pain, or discomfort related to testing), and morbidity attributed to treatment (e.g., renal toxicity, sensitivity reactions). All Key Questions include studies of high- and low-risk populations. We restricted inclusion to English-language articles and excluded studies only published as abstracts. Studies of non-human subjects were also excluded, and studies had to report original data. For Key Questions 1 through 3, we included studies conducted in the United States (U.S.). We also included studies conducted in countries with a “very high” Human Development Index44 (considered applicable to U.S populations and practice) and included studies from countries with a “high” Human Development Index if no other studies were available. For Key Questions 4 through 6 (treatments for elevated BLLs) we included studies of
asymptomatic pregnant women conducted in any country that evaluated interventions that focused on the individual or family (e.g., counseling, nutritional interventions, residential hazard control techniques and chelation therapy), but excluded studies of policies, laws or community-based interventions focused on the primary prevention of lead exposure. We included randomized controlled trials of screening and treatments, and also included controlled clinical trials on effects of therapies on health outcomes, controlled clinical trials and prospective cohort studies on harms of therapies, and studies on diagnostic accuracy of screening questionnaires or capillary sampling. The selection of literature is summarized in the literature flow diagram (Appendix A3). Appendix A4 lists excluded studies with reasons for exclusion.

Data Abstraction and Quality Rating

One investigator abstracted details about the study design, patient population, setting, screening method, interventions, analysis, followup, and results. A second investigator reviewed data abstraction for accuracy. For studies that did not report measures of diagnostic accuracy but provided the necessary data, we calculated relative risks (RR), likelihood ratios, positive and negative predictive values and 95 percent confidence intervals (CI) or p-values. Two investigators independently applied criteria developed by the USPSTF to rate the quality of each study as good, fair, or poor (Appendix A5) and resolved discrepancies by consensus.

Data Synthesis

Two independent reviewers assessed the internal validity (quality) of the body of evidence for each key question (“good,” “fair,” “poor”) using methods developed by the USPSTF, based on the number, quality and size of studies, consistency of results between studies, and directness of evidence (Table 2). Due to the limited nature of the evidence, meta-analyses were not possible and we discuss the evidence qualitatively.

External Review

The draft report has been reviewed by content experts, USPSTF members, AHRQ Project Officers, and collaborative partners, and will be posted for public comment and revised based on reviewer comments.
Chapter 3. Results

Key Question 1a. Is There Direct Evidence That Screening for Elevated Blood Lead Levels in Asymptomatic Pregnant Women Improves Health Outcomes?

Key Question 1b. Does the Effectiveness of Screening in Asymptomatic Pregnant Women Vary by Gestational Age?

As in the prior USPSTF review, no studies directly evaluated clinical benefits and harms of screening pregnant women for elevated lead levels versus no screening, or how effectiveness of screening varies according to the gestational age at which screening is performed.

Key Question 2. What Is the Accuracy of Questionnaires or Clinical Prediction Tools That Identify Pregnant Women Who Have Elevated Blood Lead Levels?

Summary

One fair-quality observational study evaluated the accuracy of a questionnaire in identifying pregnant women with elevated blood lead levels (Appendixes B1, C1). For this study, four relevant questions from the 5-question CDC questionnaire designed for identifying children at risk were used, with the exclusion of one item on point source industrial lead exposure. The study demonstrated that women with a positive response to at least one of the four questions were more likely to have elevated blood lead than those who answered negatively to all four questions (RR 2.39, 95% CI 1.17 to 4.89; p=0.01). The CDC questionnaire had a sensitivity of 75.7% in the study and a sensitivity of 46.2%. The most predictive single item was ‘home built before 1960.’

Evidence

The prior USPSTF review described one fair-quality cross-sectional study (n=314) of pregnant women in Ohio on the accuracy of the CDC lead questionnaire for screening children for risk of elevated BLLs. We did not identify any additional studies on the accuracy of instruments for identifying pregnant women with elevated BLLs, but included this study that modified the CDC questionnaire for children for use in pregnant women.

The CDC questionnaire is a five question survey developed in 1991 that aims to assess residential, household, and personal risk factors for lead exposure in children. Specific items include the age of current housing and the condition of the paint; household members and children with BLL ≥15 µg/dL; exposure through [parental] work or hobbies; and a home in close proximity to lead industry.
The included study of pregnant women used four of the five CDC questions and eliminated a question on point source lead exposure from industries not relevant to this community. This study also included three additional questions. The questions were answered based on responses to a self-administered questionnaire of 19 items and a logistic model to identify the most predictive factors. This study enrolled low-income women attending public health clinics. The majority of participants were 35 or younger, and a third were adolescents. Ninety-four percent were Medicaid eligible, 66 percent were white and 28 percent were black. Thirteen percent (N = 39) had BLLs of 10 µg/dL or greater, with a mean BLL of 12.6 µg/dL.

Based on the threshold of at least one positive answer to one of four questions, 57 percent of the enrolled women qualified as high risk for lead exposure and had a significantly increased risk for having an elevated BLL (defined as ≥10 µg/dL). The modified CDC questionnaire had a sensitivity of 75.7% and specificity of 46.2%. The Positive Likelihood Ratio was 1.4 and the Negative Likelihood Ratio was 0.52.

Using logistic regression, three specific questions were identified as predicting elevated BLLs more accurately; question 1 in the CDC set (home built before 1960 with peeling paint) and two questions added to the CDC questions (being a current smoker, and consuming >10 servings of canned food per week). The sensitivity and specificity for these questions were: 59.5% and 67.2% for house built before 1960; 56.8% and 63.0% for current smoker; and 18.9% and 91.6% for consuming more than nine servings of canned food per week. Answering ‘yes’ to any of these three questions resulted in a sensitivity of 75.7% and specificity of 41.2%. The Positive Likelihood Ratio for this 3-question set was 1.4, and the Negative Likelihood Ratio was 0.26. The exact method of determining that these three questions were the best was not clearly reported.

Limitations of this study include lack of clarity on how patients were selected, no comparison group, and answers to the evaluated questions (four CDC and an additional three questions) being derived from a separate 19-question set. It was not clear if the interpretation of the questionnaire results was done without knowledge of the BLLs and, further limiting results, was that the derived 3-item instrument was not tested in an independent cohort.

**Key Question 3. What Are the Harms of Screening for Elevated Blood Lead Levels (With or Without Screening Questionnaires) in Asymptomatic Pregnant Women?**

As in the prior report, no studies directly compared the harms of screening pregnant women for elevated lead levels in a screened population versus an unscreened population.
Key Question 4. Do Counseling and Nutritional Interventions, Residential Lead Hazard Control Techniques, or Chelation Therapy Reduce Blood Lead Levels and Rates of Gestational Hypertension in Asymptomatic Pregnant Women With Elevated Blood Lead Levels?

Summary

One fair-quality RCT of healthy pregnant women (mean baseline lead levels ~ 4 µg/dL) in Mexico found calcium supplementation associated with reduced blood levels versus placebo (difference 11%, p=0.004; levels in each group not reported). Effects were more pronounced in women with baseline blood levels ≥5 µg/dL (Appendixes B2, C2).

Evidence

The prior USPSTF report did not include any studies on effects of interventions to lower blood lead levels in asymptomatic pregnant women.

One fair-quality RCT (n=670) of healthy pregnant women less than 14 weeks gestation attending Mexican Social Security Institute prenatal clinics compared a nightly dose of 1,200 mg of calcium until delivery versus placebo.26 Women were not required to have elevated blood lead level at baseline (mean 3.8 vs. 4.1 ug/dL).

Calcium supplementation was associated with an 11% greater reduction in blood lead level than placebo (p=0.004; BLLs by group not reported).26 The difference was largest during the second trimester (14% difference, p <0.01; third trimester difference = 8%, p = 0.11). Stratifying the analysis according to baseline BLL showed greater benefit from calcium supplementation in patients with elevated BLL at baseline. In women with BLL ≥5 ug/dL at baseline, calcium supplementation was associated with a 17% greater reduction in BLL versus placebo, compared with a 7% greater reduction in those with lead levels <5 ug/dL at baseline.

Limitations of this study include unclear methods of allocation, lack of blinding of patients or outcome assessors, and small population differences at baseline, including dietary calcium intake. Loss to followup was 14% (46/334) and 18% (59/336) in the calcium and placebo groups, respectively. This was not a statistically significant difference (relative risk 0.78, 95% CI 0.55 to 1.12), but these were patients who did not contribute data on BLL for trimesters two and three.

Secondary analyses found a dose-response association between adherence with calcium supplementation and greater effects on blood lead concentration. Greater adherence (taking 50% or more of calcium doses) resulted in blood lead levels 15% lower than in the placebo group (p <0.001), taking more than 67% resulted in 19% lower levels (p <0.001) and taking more than 75% of calcium doses resulted in 24% lower lead levels (p <0.001). In women with elevated BLL at baseline, the difference between calcium and placebo in BLL reduction among more adherent women was smaller (3%) and not statistically significant.
There are no studies of the effects of other interventions to reduce elevated BLLs in pregnant women.

**Key Question 5. Do Counseling and Nutritional Interventions, Residential Lead Hazard Control Techniques, or Chelation Therapy Improve Health Outcomes in Asymptomatic Pregnant Women With Elevated Blood Lead Levels?**

As in the prior USPSTF report, no studies reported health outcomes following interventions to reduce blood lead levels in asymptomatic pregnant women.

**Key Question 6. What Are the Harms of Interventions in Asymptomatic Pregnant Women With Elevated Blood Lead Levels?**

The prior USPSTF found no studies on harms of interventions for lowering elevated blood lead levels in pregnant women. A subsequent RCT on effects of calcium supplementation on blood lead levels in pregnant women did not report harms (see Key Question 4).26

**Contextual Questions**

We identified no studies on the reliability of venous blood lead testing at various lead levels in pregnant women, the association between reduced blood lead levels and improved health outcomes in asymptomatic pregnant women with elevated blood lead concentrations, or any studies addressing risk prediction tools that identify communities at highest risk for lead exposure during pregnancy.
Chapter 4. Discussion

Summary of Review Findings

Evidence to determine the clinical benefits and harms of screening pregnant women for elevated blood lead levels versus not screening is extremely limited. No evidence directly evaluated the health benefits and harms of screening or the health outcomes or harms of interventions to treat elevated blood lead levels in pregnant women. Important gaps in the indirect chain of evidence include poor diagnostic accuracy of instruments to identify women at risk of elevated BLLs to guide targeted screening and limited evidence and no clear effects of interventions in pregnant women.

The one observational study used a questionnaire designed to evaluate lead exposure in children and found poor diagnostic accuracy with likelihood ratios that are not informative. No studies of questionnaires for lead exposure during pregnancy have been published. Accurate risk assessment instruments would facilitate improved targeted screening strategies.

Effectiveness of nutritional interventions for pregnant women with elevated blood lead levels is limited. There were no studies of chelation or residential interventions in pregnant women. There were no available studies to address the remaining key questions or the contextual questions. At present, no studies address when to screen during pregnancy and how to treat women identified with elevated blood lead.

Table 2 summarizes the evidence reviewed for this update.

Contextual Issues

Evidence on the intra-individual and interlaboratory reliability of blood lead level testing would be helpful for interpreting testing results, informing technical standards, and informing testing protocols and strategies. No risk prediction tools were identified that could be used in primary care practices to target screening of pregnant women living in communities at high risk for lead exposure.

Generalizability

The findings from the two studies included in this report are not generalizable. The study of the CDC questionnaire aimed at assessing risk in children had poor diagnostic accuracy in a pregnant population. The single study of calcium supplementation to reduce BLLs was conducted in low to moderate-income women in Mexico, with a high proportion of enrolled women regularly using lead-glazed ceramics regularly for cooking meals (35%) and did not limit enrollment to women with asymptomatic elevated BLLs at baseline. It is unclear whether this intervention would have similar effectiveness in a U.S population given potential differences in environments and nutrition. However, identifying culturally linked sources of lead exposure in
U.S pregnant populations could have an impact on risk.

**Limitations**

The major limitation of this review was the overall lack of evidence to address all key questions. Other limitations of this review include restriction to English-language articles, which could result in language bias. However, we did not identify non–English-language studies in our searches that otherwise met inclusion criteria. Despite searching for updated data, the available studies may represent outdated risk factors and treatments that are not as relevant today. We included non-randomized studies to evaluate the effectiveness of interventions for elevated blood levels. Such studies are more susceptible to confounding and bias, as reflected in the quality ratings we assigned. We did not attempt meta-analysis, given small numbers of studies and clinical and methodological diversity within the studies, and were unable to formally assess for publication bias due to the small number of studies.

**Evidence for Priority Populations, Particularly Racial/Ethnic Minorities**

Elevated lead levels primarily impact socioeconomically disadvantaged and minority populations. Different sources of lead exposure than have been previously considered are emerging in these populations, yet research in these groups remains limited.\(^{31,32,46}\) Exposures related to community water sources, lead plumbing in schools, and factory emissions affecting neighborhood soil quality are just some of the emerging factors that are not widely incorporated into current screening questionnaires. Additional research is warranted to validate these potential associations in specific geographic locations and among at-risk populations as the impact of these exposures on blood lead concentration in pregnant women is not well established. Culturally linked sources of lead poisoning such as imported candy, pottery and cosmetics, specific to subpopulations living in the U.S., may also provide information about risk in minority populations. For example, traditional folk remedies and imported digestive remedies that may contain high levels of lead are not monitored by the U.S. Food and Drug Administration (FDA), and are more common in Hispanic and Asian populations.\(^{31,32}\) Non-traditional sources of lead exposure that come from items manufactured in other countries, such as leaded pots and pans, cosmetics, medicines, ceramics, and leaded crystal may also pose additional risk since little regulation exists to monitor, identify, and control these non-paint exposures. Pregnant women who are exposed to these less well recognized sources of lead exposure may also live in housing that has higher risk for lead exposure. The potential for multiple sources of risk associated with minority communities calls for a more focused strategy to deal with population-specific risks.

**Future Research**

Elevated blood lead levels are associated with serious health consequences. Additional research is urgently needed to better inform decisions regarding screening in pregnant women, including evaluations of newer testing methods and techniques. Development of questionnaires that
incorporate current risk factors for elevated lead levels with validation in contemporary populations of pregnant women in the U.S is necessary. Ideally, randomized trials would recruit pregnant women from a range of racial, ethnic, and socioeconomic strata, and evaluate the effects of screening on improving health outcomes as well as short and long term harms. These studies should address risk factors in pregnant women including occupational exposures, be tested in contemporary cohorts, and be validated in independent cohorts. An initial step would include conducting randomized controlled trials that evaluate effective interventions for lowering BLLs in pregnant women and would report intermediate and health outcomes, outcomes in newborns, and harms in both women and infants. Research on the intra-individual and interlaboratory reliability of blood lead level testing would be helpful for informing testing strategies.

Conclusions

Evidence on the benefits and harms of screening pregnant women for elevated blood lead levels is extremely limited, with no evidence on effects of screening or interventions for lowering elevated blood lead levels in pregnant women on health outcomes.

Interventions include counseling families to reduce lead exposure, nutritional interventions, residential hazard control techniques, and chelation therapy.

We will include outcomes measured in family members (e.g., siblings, pregnant women in the same household) who are subsequently identified as having elevated blood lead levels after the index family member was found to have an elevated blood lead level during screening.

| American College of Obstetricians and Gynecologists (ACOG) 2012 | Blood lead testing of all pregnant women in the United States is not recommended. Obstetric health care providers should consider the possibility of lead exposure in individual pregnant women by evaluating risk factors for exposure as part of a comprehensive health risk assessment and perform blood lead testing if a single risk factor is identified. Assessment of lead exposure should take place at the earliest contact with the pregnant patient. The ACOG guidelines refer to CDC recommendations regarding risk factors for exposure. |

Appendix A5. U.S. Preventive Services Task Force Quality Rating Criteria

Systematic Reviews

Criteria:
- Comprehensiveness of sources considered/search strategy used
- Standard appraisal of included studies
- Validity of conclusions
- Recency and relevance (especially important for systematic reviews)

Definition of ratings based on above criteria:

**Good:** Recent, relevant review with comprehensive sources and search strategies; explicit and relevant selection criteria; standard appraisal of included studies; and valid conclusions

**Fair:** Recent, relevant review that is not clearly biased but lacks comprehensive sources and search strategies

**Poor:** Outdated, irrelevant, or biased review without systematic search for studies, explicit selection criteria, or standard appraisal of studies

Case-Control Studies

Criteria:
- Accurate ascertainment of cases
- Nonbiased selection of cases/controls, with exclusion criteria applied equally to both
- Response rate
- Diagnostic testing procedures applied equally to each group
- Measurement of exposure accurate and applied equally to each group
- Appropriate attention to potential confounding variables

Definition of ratings based on above criteria:

**Good:** Appropriate ascertainment of cases and nonbiased selection of case and control participants; exclusion criteria applied equally to cases and controls; response rate equal to or greater than 80 percent; accurate diagnostic procedures and measurements applied equally to cases and controls; and appropriate attention to confounding variables

**Fair:** Recent, relevant, and without major apparent selection or diagnostic workup bias, but response rate less than 80 percent or attention to some but not all important confounding variables

**Poor:** Major selection or diagnostic workup bias, response rate less than 50 percent, or inattention to confounding variables
RCTs and Cohort Studies

Criteria:
- Initial assembly of comparable groups:
  - For RCTs: Adequate randomization, including first concealment and whether potential confounders were distributed equally among groups
  - For cohort studies: Consideration of potential confounders, with either restriction or measurement for adjustment in the analysis; consideration of inception cohorts
- Maintenance of comparable groups (includes attrition, cross-overs, adherence, contamination)
- Important differential loss to followup or overall high loss to followup
- Measurements: equal, reliable, and valid (includes masking of outcome assessment)
- Clear definition of interventions
- All important outcomes considered
- Analysis: adjustment for potential confounders for cohort studies or intention-to-treat analysis for RCTs

Definition of ratings based on above criteria:

**Good:** Meets all criteria: Comparable groups are assembled initially and maintained throughout the study (followup ≥80%); reliable and valid measurement instruments are used and applied equally to all groups; interventions are spelled out clearly; all important outcomes are considered; and appropriate attention to confounders in analysis. In addition, intention-to-treat analysis is used for RCTs.

**Fair:** Studies are graded “fair” if any or all of the following problems occur, without the fatal flaws noted in the “poor” category below: Generally comparable groups are assembled initially, but some question remains whether some (although not major) differences occurred with followup; measurement instruments are acceptable (although not the best) and generally applied equally; some but not all important outcomes are considered; and some but not all potential confounders are accounted for. Intention-to-treat analysis is used for RCTs.

**Poor:** Studies are graded “poor” if any of the following fatal flaws exists: Groups assembled initially are not close to being comparable or maintained throughout the study; unreliable or invalid measurement instruments are used or not applied equally among groups (including not masking outcome assessment); and key confounders are given little or no attention. Intention-to-treat analysis is lacking for RCTs.

Diagnostic Accuracy Studies

Criteria:
- Screening test relevant, available for primary care, and adequately described
- Credible reference standard, performed regardless of test results
- Reference standard interpreted independently of screening test
- Indeterminate results handled in a reasonable manner
- Spectrum of patients included in study
Appendix A5. U.S. Preventive Services Task Force Quality Rating Criteria

- Sample size
- Reliable screening test

Definition of ratings based on above criteria:

**Good:** Evaluates relevant available screening test; uses a credible reference standard; interprets reference standard independently of screening test; assesses reliability of test; has few or handles indeterminate results in a reasonable manner; includes large number (>100) of broad-spectrum patients with and without disease

**Fair:** Evaluates relevant available screening test; uses reasonable although not best standard; interprets reference standard independent of screening test; has moderate sample size (50 to 100 subjects) and a “medium” spectrum of patients

**Poor:** Has a fatal flaw, such as: Uses inappropriate reference standard; improperly administers screening test; biased ascertainment of reference standard; has very small sample size or very narrow selected spectrum of patients

- Jennifer A. Lowry, MD, Chief, Section of Toxicology and Environmental Health, Children’s Mercy
- Suril Mehta, MPH, Health Scientist, Office of the Report on Carcinogens, U.S. National Toxicology Program, National Institute of Environmental Health Sciences
- Matthew Strickland, PhD, MPH, Associate Professor of Epidemiology, School of Public Health Sciences, University of Nevada, Reno
- Federal Partners from the United States Environmental Protection Agency
  - Ruth A. Etzel, MD, PhD, Director, Office of Children’s Health Protection, United States Environmental Protection Agency
- Additional Federal Partners from the Centers for Disease Control and Prevention
  - Brandy Peaker, MD, MPH, CDC Liaison, Centers for Disease Control and Prevention

Note: Reviewers provided comments on a prior version of the draft report and may or may not agree with the report findings.
