AHRQ Publication No. 15-05220-EF-1
June 2016
This report is based on research conducted by the Kaiser Permanente Research Affiliates Evidence-based Practice Center (EPC) under contract to the Agency for Healthcare Research and Quality (AHRQ), Rockville, MD (Contract No. HHSA-290-2012-00015-I-EPC4, Task Order 4). The findings and conclusions in this document are those of the authors, who are responsible for its contents; and do not necessarily represent the views of AHRQ. Therefore, no statement in this report should be construed as an official position of AHRQ or of the U.S. Department of Health and Human Services.

The information in this report is intended to help health care decisionmakers—patients and clinicians, health system leaders, and policymakers, among others—make well-informed decisions and thereby improve the quality of health care services. This report is not intended to be a substitute for the application of clinical judgment. Anyone who makes decisions concerning the provision of clinical care should consider this report in the same way as any medical reference and in conjunction with all other pertinent information (i.e., in the context of available resources and circumstances presented by individual patients).

The final report may be used, in whole or in part, as the basis for development of clinical practice guidelines and other quality enhancement tools, or as a basis for reimbursement and coverage policies. AHRQ or U.S. Department of Health and Human Services endorsement of such derivative products may not be stated or implied.

None of the investigators has any affiliations or financial involvement that conflicts with the material presented in this report.

**Acknowledgments**

The authors gratefully acknowledge the following individuals for their contributions to this project: Smyth Lai, MLS, for creating and conducting the literature searches; Kevin Lutz, MFA, for his editorial assistance; Nadia Redmond, MSPH, for her assistance with data abstraction; Jennifer S. Lin, MD, for her review of the final report; Tina Fan, MD, MPH, at AHRQ; current and former members of the U.S. Preventive Services Task Force who contributed to topic deliberations; and Hanna Bloomfield, MD, MPH, Melinda A. Cavicchia, MD, MPH, David Chelmow, MD, Esther Eisenberg, MD, MPH, Tara Jatlaoui, MD, MPH, Barnett Kramer, MD, MPH, Giang Nguyen, MD, MPH, Mary Roary, PhD, Mona Saraiya, MD, MPH, Sherri Stewart, PhD, and Naomi Tepper, MD, MPH, for their expert feedback on this report. The authors thank Barnett Kramer, MD, MPH, and Paul Pinsky, PhD for providing the unpublished data from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) participants undergoing ovarian palpation.
Structured Abstract

**Background:** In light of recent guideline changes in the periodicity of cervical cancer screening, there is uncertainty surrounding the role of the routine screening pelvic examinations during annual prevention visits.

**Purpose:** We conducted this systematic review to support the U.S. Preventive Services Task Force in creating its recommendation on the periodic screening pelvic examination. Our review addresses three questions: 1) What is the direct evidence for the effectiveness of the pelvic examination in reducing all-cause mortality, cancer- and disease-specific morbidity and mortality, and improving quality of life?; 2) What are the test performance characteristics of the pelvic examination in screening for gynecologic cancers and other gynecologic conditions?; 3) What are the adverse effects of screening using the pelvic examination?

**Data Sources:** We searched MEDLINE, PubMed (publisher-supplied references only), and the Cochrane Central Register of Controlled Trials to identify literature that was published from the earliest date indexed (1946 for MEDLINE) to January 13, 2016. We supplemented our searches with reference lists from relevant existing systematic reviews, suggestions from experts, and ClinicalTrials.gov to identify ongoing trials.

**Study Selection:** Two investigators independently reviewed identified abstracts and full-text articles against a set of *a priori* inclusion and quality criteria.

**Data Analysis:** One investigator abstracted data into an evidence table and a second investigator confirmed these data. We qualitatively synthesized the data for each key question; quantitative synthesis was not appropriate due to heterogeneity and the low number of trials for any given intervention and outcome.

**Results:** We found no studies that assessed the effectiveness of the pelvic examination in reducing all-cause mortality, cancer- and disease-specific morbidity and mortality, or improving quality of life. For four conditions, we identified a total of eight diagnostic accuracy studies that examined test characteristics for the screening pelvic examination: ovarian cancer (k=4), bacterial vaginosis (k=2), trichomoniasis (k=1), and genital herpes (k=1). These eight studies also provided information on the harms of screening using the pelvic examination (false-positive and false-negative results). One large good quality RCT reported additional diagnostic workup, surgeries, and any complications occurring one year after abnormal ovarian palpation. An additional cohort study also assessed harms (urinary symptoms). The low prevalence of ovarian cancer in the general population consistently resulted in low positive predictive values. In these four ovarian cancer screening studies, with over 26,000 screened patients, >96 percent of the positive test results were false positives, depending on the study design and management protocols. Surgery rates resulting from an abnormal pelvic examination ranged from 5 percent to 36 percent at one year with the largest study reporting an 11 percent surgery rate and 1 percent complication rate within one year of an abnormal screening pelvic examination. Each diagnostic accuracy study for bacterial vaginosis, trichomoniasis, and genital herpes was performed in a high-prevalence population with high proportions of symptomatic patients and reported accuracy characteristics for individual physical examination findings, thereby limiting any conclusions.
that could be made regarding the screening accuracy or adverse effects of the pelvic examination in asymptomatic primary care populations.

**Conclusions:** There is no direct evidence on the overall benefits and harms of the pelvic examination as a one-time or periodic screening test. In addition, there is limited evidence regarding the diagnostic accuracy and harms of the routine screening pelvic examination to guide practice in asymptomatic primary care populations. Research is needed to illuminate how recent changes in cervical cancer screening periodicity may influence women’s access to other evidence-based preventive services in the primary care setting and to create best practices for achieving high rates of uptake for these recommended services.

Chapter 1. Introduction

In recent years, evidence reviews and expert consensus have been the basis for changes to longstanding practices of preventive gynecologic screening. There have been several monumental changes in women’s health in the past decade, including a shift away from annual cervical cancer screening and a move towards urine-based screening for sexually transmitted infections (STIs) (specifically, chlamydia and gonorrhea) among young women. Later initiation of cervical cancer screening and longer intervals between Papanicolaou (Pap) tests were recommended by the American College of Obstetricians and Gynecologists (ACOG) in 2009. Current guidelines from the U.S. Preventive Services Task Force and ACOG recommend screening for cervical cancer beginning at age 21 and every 3 years thereafter until age 30; after age 30, 5-year intervals are recommended for most women not at high risk of this disease. Prior to these changes, annual visits for cervical cancer screening provided an opportunity for routine examination of the external and internal reproductive organs. As the intervals for cervical cancer screening have been extended, the independent clinical value of the pelvic examination has been increasingly questioned and debated and a variety of recommendations have been issued. Currently, a central question in women’s primary health care is whether women attending routine visits without gynecologic symptoms would benefit from a screening pelvic examination.

Background

The pelvic examination consists of visual and physical assessments of female reproductive organs. The pelvic examination may be performed for the purpose of screening for a specific condition, diagnostic evaluation of gynecological symptoms, or disease surveillance. Typically, the screening pelvic examination for asymptomatic women includes a visual inspection of the external genitalia; a speculum examination of the vagina and cervix; bimanual examination of the adnexa, uterus, and cervix; and may include the a rectovaginal examination. In addition, tests for cervical cancer screening (i.e., Pap test, human papilloma virus [HPV] test) may be collected during a routine pelvic examination. Historically, screening pelvic examinations were part of routine annual gynecological examinations during which Pap test collections occur. Even after most professional societies endorsed less frequent cervical cancer screening, many women continued to present annually for routine gynecologic care. Routine pelvic examination is a longstanding practice that some patients and providers may view as an opportunity to discuss a broad range of sexual and reproductive health issues.

In contrast to most screening tests, the pelvic examination does not identify a unique disease entity. Multiple gynecologic conditions (malignant and benign) could plausibly be detected by pelvic examination or are cited by providers as reasons for conducting a pelvic examination, including: cervical, endometrial, ovarian, vaginal, and vulvar cancer; bacterial vaginosis, candidiasis, chlamydia, gonorrhea, genital warts, genital herpes, pelvic inflammatory disease (PID), and trichomoniasis; atrophic vaginitis, cervical polyps, endometriosis, ovarian cysts, pelvic organ prolapse, uterine fibroids, and vulvar lichen sclerosis (Table 1). Each disease can be considered individually for evidence-based screening recommendations by weighing the...
potential benefits and risks based on test-, disease-, and population-specific factors. Specifically, each condition can be evaluated for prevalence and burden, typical clinical presentation, screening test accuracy during the asymptomatic phase, and treatment benefits in early stage disease. Moreover, the gynecologic conditions potentially detectable with the pelvic examination vary by target population—some conditions occur only in specific age groups (adolescent, young adult, pregnant, premenopausal, or postmenopausal) or primarily among women at increased risk based on behavioral or genetic factors.

The value of early detection of asymptomatic disease for these gynecologic conditions varies considerably. For example, identifying and treating screen-detected asymptomatic BV or vaginal candidiasis in non-pregnant women may have little clinical benefit compared to diagnosis and treatment during symptomatic stages. Likewise, for asymptomatic atrophic vaginitis, cervical polyps, or uterine fibroids, the clinical significance and therefore the role for early treatment is unclear in the absence of symptoms. For some gynecologic conditions, such as cervical cancer, gonorrhea, and chlamydia, there are alternative and well-established evidence-based screening tests with superior accuracy compared to the pelvic examination (i.e., Pap/HPV test for cervical cancer and nucleic acid amplification tests [NAAT] for gonorrhea and chlamydia). In theory, some gynecologic cancers, such as those of the ovaries, vulva, and vagina, might have an improved treatment prognosis if detected in earlier asymptomatic stages and there is currently no alternative, effective screening strategy. In contrast, endometrial cancer is frequently symptomatic in its early stages and the screening pelvic examination is unlikely to detect early-stage cancer since it is not palpable or visible on examination. Some conditions, like endometriosis, clinically present in the context of dysmenorrhea or infertility diagnostic work-up. Likewise, pelvic floor dysfunction or pelvic organ prolapse may be diagnosed and graded for severity only after history taking reveals urinary incontinence or retention. Furthermore, advances in ultrasound technology over the past few decades, which is more sensitive than pelvic examination for detecting pelvic masses, have transformed the detection and surveillance of pelvic masses.

**Current Clinical Practice in the United States**

In 2010, 62.8 million pelvic examinations were performed in the United States. Sixty-eight percent of surveyed U.S. obstetrician-gynecologists routinely perform a pelvic examination, and 78 percent of all surveyed physicians (including family/general practitioners and internists) believed that pelvic examination is a useful screening test for gynecologic cancers. In a nationally representative survey of obstetrician-gynecologists, approximately 50 percent reported that performing a bimanual examination to detect ovarian cancer was very important, and approximately 20 and 25 percent thought it was very important for the detection of uterine and cervical cancer, respectively. For other gynecological conditions, over 50 percent thought the bimanual examination was very important for detecting benign ovarian conditions, nearly 60 percent thought it was very important to detect benign uterine conditions, and about 30 percent reported it was very important in detecting both subclinical PID and uterine position. Almost all of the surveyed physicians indicated that they would perform a bimanual examination during a routine visit with an asymptomatic patient.
The Centers for Medicare and Medicaid Services cover screening pelvic examinations as a stand-alone billable service, without patient copayment, every 24 months for all asymptomatic women and yearly for high-risk women (i.e., women at high risk for vaginal or cervical cancer or women of childbearing age with a vaginal or cervical abnormality found on pelvic examination in the preceding 3 years).\(^\text{18}\)

Unpublished data from 2008 through 2010 indicate that the majority of preventive care visits to obstetrician-gynecologists (76%) included a pelvic examination. In contrast, only a quarter of visits to family medicine physicians (25%) and even fewer to internal medicine physicians (14%) included a pelvic examination (unpublished NAMCS/NHAMCS analyses by Esther Hing [NCHS/CDC], January 22, 2015).

**Recommendations of Other Groups**

Professional organizations vary in their recommendations regarding routine screening pelvic examinations (Table 2). The American College of Physicians recently released a guideline recommending that practitioners not perform screening pelvic examinations (except for cervical cancer screening by visual inspection of the cervix and cervical swabs) in asymptomatic, average-risk women for the purpose of screening for gynecologic cancers, PID, and other benign gynecologic conditions.\(^\text{9}\) The basis of this recommendation was a systematic review that identified no benefits of pelvic examination and but some exposure to unnecessary and avoidable harms. The recommendation does not apply to women who present with symptoms (e.g., abnormal bleeding, pain), in which case the pelvic examination would be an appropriate diagnostic procedure to consider. The guideline is endorsed by the American Academy of Family Physicians.\(^\text{19}\)

ACOG recommends an annual pelvic examination for women 21 years or older but acknowledges there is no evidence in support of or against this recommendation.\(^\text{8}\) Furthermore, they noted that this examination is not necessary to prescribe hormonal contraception in healthy women or to screen for STIs. For females younger than 21 years, ACOG recommends a pelvic examination if indicated by medical history. For symptomatic patients aged 21 or older, joint decisionmaking with the clinician and patient is advised to determine whether pelvic examination should be performed. In 2015, ACOG convened the Well-Woman Task Force (WWTF) and released recommendations for the well-woman visit.\(^\text{20}\) The WWTF recommended that external examinations may be performed annually in healthy patients 21 years or older, but the inclusion of speculum and bimanual examination for asymptomatic women without specific indications (e.g., cervical cancer screening) should be a shared, informed decision between the patient and provider. The WWTF categorized their pelvic examination recommendation as “qualified”, meaning that it is based on expert opinion rather than clinical evidence.

Despite the inconsistent recommendations for screening pelvic examinations, the available guidelines from national organizations regarding screening for individual gynecologic conditions are similar (Table 3). Recommendations on the types of and timing of tests that are effective for cervical cancer, gonorrhea, or chlamydia screening are consistent, as are recommendations against screening for ovarian cancer using currently available approaches (including the
bimanual pelvic examination). Recommendations available for other gynecologic conditions are few.

**Previous Related USPSTF Topics**

The United States Preventive Services Task Force (USPSTF) has not made a prior recommendation regarding the routine use of screening pelvic examinations in unselected asymptomatic women, but it has issued several recommendations for screening for benign and malignant gynecologic conditions, including ovarian cancer, cervical cancer, herpes, chlamydia, gonorrhea, and BV (Table 4).
Chapter 2. Methods

Scope and Purpose

The USPSTF will use this evidence review to issue a new recommendation statement on periodic screening pelvic examinations in unselected, asymptomatic, nonpregnant adult females. This review addresses the benefits and harms of screening with the pelvic examination for gynecologic cancers and conditions as well as the diagnostic accuracy of the pelvic examination in detecting individual gynecologic cancers and conditions.

While the pelvic examination is common for adolescent and pregnant women, these populations were specifically excluded from the scope of this review. The purpose of conducting the pelvic examination in unselected nonpregnant adult women may differ from that in special populations of adolescents (e.g., Tanner staging, congenital abnormality case-finding) for pregnant women (e.g., pregnancy dating, pelvic outlet adequacy, cervical dilation checks). Likewise, screening for congenital gynecological conditions was excluded because this review focuses on routine periodic screening and many of the congenital conditions would be detected at the symptomatic stage, during pregnancy, at infertility work-up, or incidentally during cervical cancer screening.

Further, the USPSTF previously determined that there is good evidence for primary screening approaches for cervical cancer, gonorrhea, and chlamydia. Since the pelvic examination alone is less accurate than the existing screening approaches for these conditions (i.e., NAAT for gonorrhea and chlamydia, Pap/HPV co-testing for cervical cancer), these conditions were not included in the scope of this review.

Key Questions and Analytic Framework

The analytic framework is presented in Figure 1.

Key Questions

1. What is the direct evidence for the effectiveness of the pelvic examination in a) reducing all-cause mortality, b) reducing cancer- and disease-specific morbidity and mortality, and c) improving quality of life?
2. What are the test performance characteristics of the pelvic examination (sensitivity, specificity, and positive and negative predictive values) in screening for gynecologic cancers and other gynecologic conditions?
3. What are the adverse effects of screening pelvic examination?
Data Sources and Searches

We searched MEDLINE, PubMed (publisher-supplied references only), and the Cochrane Central Register of Controlled Trials to locate relevant studies for all three key questions. We searched for articles from the earliest date indexed (1946 for MEDLINE) through January 13, 2016. We supplemented our database searches with experts’ suggestions and by reviewing reference lists from all other recent existing systematic reviews. We also searched selected sources of grey literature, including ClinicalTrials.gov and the WHO International Clinical Trials Registry Platform, for ongoing trials. We requested unpublished Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial data from the National Cancer Institute.

Study Selection

Two investigators independently reviewed 8677 titles and abstracts by using an online platform (abstrackr\textsuperscript{21}) and 315 articles (Appendix A Figure 1) with specified inclusion criteria (Appendix A Table 1). We resolved discrepancies through consensus and consultation with a third investigator. We excluded articles that did not meet inclusion criteria or those we rated as poor quality. To ensure that studies using the pelvic examination as a secondary screening test (e.g., ovarian cancer screening studies using CA-125 and ultrasound technology that also included a pelvic examination component) were not missed, we were more inclusive during the review of abstracts and titles. As a result, many studies were excluded at the full-text review. Appendix B lists all excluded trials.

Eligible studies included unselected adult females who were not symptomatic or pregnant. We excluded studies that were conducted solely with symptomatic populations.

For the greatest applicability to U.S. practice, we focused on studies conducted in developed countries, as defined by “very high” development according to the 2014 United Nations Human Development Index.\textsuperscript{22} We included only studies that published their results in English because of resource constraints.

Any study that examined the effects of pelvic examination on all-cause mortality, cancer- or disease-specific morbidity or mortality, or quality of life was eligible for inclusion in our review. Further, studies examining the screening accuracy of the pelvic examination in a single encounter or as a periodic program of screening also were eligible.

Quality Assessment and Data Abstraction

At least two reviewers critically appraised all articles that met the inclusion criteria using the Newcastle Ottawa Scales for cohort and case-control studies\textsuperscript{24} and Quality Assessment of Diagnostic Accuracy Studies (QUADAS) I and II for studies of diagnostic accuracy\textsuperscript{25, 26} adapted to align with the USPSTF’s design-specific quality criteria\textsuperscript{23} (Appendix A Table 2). We rated articles as good, fair, or poor quality. In general, a good-quality study met all criteria, indicating low risk of bias. A fair-quality study did not meet, or it was unclear if it met, at least one
criterion and also had no known important limitations that could invalidate its results. A poor-quality study had a single fatal flaw or multiple important limitations. We excluded poor-quality studies from this review. Disagreements about critical appraisal were resolved by consensus and, if needed, consultation with a third independent reviewer.

One reviewer extracted key elements of included studies into standardized evidence tables. A second reviewer checked the data for accuracy. Evidence tables were tailored for each key question and to specific study designs and/or specific screening tests. Tables generally included details on study quality, setting and population (e.g., country, inclusion criteria, age, sex, race/ethnicity, symptomatic), screening test and protocol (e.g., who administered, how it was administered, definition of test positive), reference standard or comparator (if applicable), length of followup, and outcomes (e.g., mortality, sensitivity and specificity, harms).

Data Synthesis and Analysis

We synthesized results by key question and type of screening test. We used a standardized summary of evidence table to describe the overall strength of evidence for each key question. This table included the number and design of included studies, summary of results, consistency or precision of results, reporting bias, summary of study quality, limitations of the body of evidence, and applicability of findings.

The results are organized by key question. Since seven of the eight included studies reported outcomes for both KQ2 (accuracy) and KQ3 (harms), we present the results for both KQ2 and KQ3 together for each disease condition. An exception was a single additional study on harms in a section entitled “other harms.”

Key Question 1

There were no studies found for KQ1.

Key Questions 2 and 3

This combined question focused on the one-time test performance of a single pelvic examination for a single condition. We organized our synthesis by condition and discuss the harms of examination due to false-positive results or further diagnostic workup. We calculated sensitivity and specificity in Stata (version 13.1, Stata Corp LP, College Station, TX) using Jeffrey’s confidence intervals. We used 2×2 tables constructed from data reported in the primary studies. If the observed sensitivity or specificity was 100 percent, only the lower 95 percent confidence interval was calculated. In many cases the data presented in our report differ slightly from the published paper because of these calculations. Since there was a limited number of studies for each condition, no pooled analyses were conducted.
Key Question 3

Due to the limited number of studies that were included only for KQ3, these results are summarized qualitatively.

Expert Review and Public Comment

The draft research plan was posted for public comment on the USPSTF website from December 4, 2014, through January 7, 2015. After that feedback was reviewed, the rectovaginal examination was included as a component of the pelvic examination. No other substantive changes were made. The full draft report was also reviewed by invited content experts and federal partners. A full draft report will be posted for public comment along with the USPSTF draft recommendation statement.

USPSTF and AHRQ Involvement

The authors worked with four USPSTF liaisons throughout the review process to develop and refine the analytic framework. These liaisons also helped to develop the key questions and to resolve scope issues for the final evidence synthesis.

This research was funded by AHRQ under a contract to support the work of the USPSTF. AHRQ staff provided oversight for the project, reviewed the draft report, and assisted with the federal partner review of the draft report.
Chapter 3. Results

Key Question 1. What Is the Direct Evidence for the Effectiveness of the Pelvic Examination in a) Reducing All-Cause Mortality, b) Reducing Cancer- and Disease-Specific Morbidity and Mortality, and c) Improving Quality of Life?

We found no studies that assessed the effectiveness of pelvic examination in reducing all-cause mortality, reducing cancer- and disease-specific morbidity and mortality, or improving quality of life.

Key Questions 2 and 3. What Are the Test Performance Characteristics of the Pelvic Examination (Sensitivity, Specificity, and Positive and Negative Predictive Values) in Screening for Gynecologic Cancers and Other Gynecologic Conditions? What Are the Adverse Effects of Screening Using the Pelvic Examination?

We found four studies examining the accuracy of the pelvic examination to detect ovarian cancer, two studies for bacterial vaginosis, and one study each for trichomoniasis and genital herpes. All of these accuracy studies (k=8) were included for harms (false positive rates and resulting diagnostic workup) and one additional study was included for other harms.

Ovarian Cancer

Summary of Findings

Despite limitations of the evidence, the low prevalence of ovarian cancer in the general population consistently resulted in low positive predictive values (PPVs) for the screening pelvic examination in detecting ovarian cancer. Based on a large study of over 20,000 women, sensitivity is low (<5%) for the detection of ovarian cancer. Considering all four included screening studies, we could not estimate accuracy with precision due to rarity of the disease, few studies, and short follow-up time in most studies. In the evidence we reviewed, surgery due to abnormal pelvic examination results ranged from 5 to 36 percent of women, depending on the study design and management protocols.

Study Characteristics

We identified one good-quality and three fair-quality studies (n=26,432) that examined the screening accuracy of pelvic examination in identifying ovarian cancer (2016 personal communication with Dr. Paul Pinsky, National Cancer Institute; unreferenced, see...
Acknowledgements). One large multicenter US RCT, the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO), recruited average risk women aged 55-74 years from the community with an overall aim of examining the benefits and harms of ovarian cancer screening using a combination of three modalities: CA-125, transvaginal ultrasound, and ovarian palpation/rectovaginal examination (ovarian palpation was dropped 5 years after trial recruitment began because no ovarian cancers were detected solely based on an abnormal ovarian palpation examination). The other three studies, conducted in Greece, Australia, and the United Kingdom, primarily recruited average-risk women aged 40 to 45 years and older from the community, but none excluded women with family history of ovarian cancer, and one actively recruited younger women with family history of ovarian cancer (Table 5). One recruited all or nearly all postmenopausal women based on lower age limit of 55 years and one specifically recruited postmenopausal women aged over 45 years. The PLCO trial excluded women with prior ovarian, lung or colon cancer. Two studies excluded women with a history of ovarian cancer, any malignancy, or bilateral oophorectomy. The fourth study recruited apparently healthy women without exclusions, and any women with a past history of cancer had to be in remission to participate. None of the studies excluded women with a family history of ovarian cancer. The number of participants who received a pelvic examination ranged from 1010 to 20,872 across the four studies.

One study defined the test as bimanual ovarian palpation plus rectovaginal exam. One study clearly defined the index pelvic examination test as the bimanual and speculum examination, while the other two studies did not define the index test beyond “pelvic exam” or “vaginal exam.” Two studies specified that experienced gynecologists or examiners performed the examination, another stated that a single examiner performed all examinations, and the third that one of two physicians examined all women. Only one study specified the ultrasonography operator as a gynecologist specializing in ultrasonography. In the PLCO trial, all participants received the bimanual ovarian palpation and rectovaginal examination in addition to a CA-125 and transvaginal ultrasound with screening tests repeated annually. In the PLCO trial, women who received the ovarian palpation/rectovaginal examination had a mean of 2.4 examinations (with no more than 4 examinations) over the initial 5 years of the trial period when this examination was a part of the screening intervention protocol. In three of the studies, all women had an examination with CA-125 and only those with either abnormal pelvic examination findings or abnormal CA-125 results then underwent transvaginal or abdominal ultrasonography. These three studies used different thresholds for acceptable CA-125 levels (>30 U/ml, >35 U/ml, ≥35 U/ml). Likewise, these three studies used differing thresholds to define an abnormal reference ultrasonography result (18 ml/8 ml in pre- and postmenopausal women, respectively, >6 cm, >8.8 ml). For the PLCO trial, cancer incidence followup at 1 year and up to 5 years were reported as captured in the SEER tumor registry, medical records, and patient questionnaire. For the other three studies, followup at 1 year consisted of a postal questionnaire for all patients or for those with normal pelvic examination findings and CA-125 levels; a fourth study additionally measured CA-125 levels at 1 year for those with normal baseline pelvic examination and CA-125 results. Any patients with abnormal CA-125 levels and normal ultrasonography findings were followed with serial CA-125 and/or ultrasonography every 3 to 6 months. For all four studies, any abnormal results were referred for further management.
Mean or median age ranged from 51 to 63 years. Forty-three percent and 65 percent of participants were postmenopausal in the two studies reporting menopausal status. In the other 2 studies, all or nearly all were postmenopausal.

Yield and Accuracy

Ovarian cancer prevalence was reported as 0.1 percent in three studies (2016 personal communication with Dr. Paul Pinsky) and 0.04 percent in one study; the longer followup from the PLCO trial (up to 5 years) reported a 0.3 percent prevalence of ovarian cancer (2016 personal communication with Dr. Paul Pinsky) (Table 6). Focusing on comparable 1 year data from the four studies, the proportion of participants with positive pelvic examination results ranged from 1.2 to 8.7 percent. Sensitivity was reported as 100 percent in two of the studies (up to two ovarian cancer cases were palpable on pelvic exam) and as 0 percent in the study where the single case of ovarian cancer was not detected on the pelvic exam. The PLCO trial reported a sensitivity of 4.3 percent and 2.8 percent from the first screening examination at 1 year and up to five years followup, respectively. In this trial, over the multiple rounds of screening, with a mean number of screens of 2.4 (range 1-4 screens), there were 91 cancers within five years of a screening examination and 88 (96.7%) were not detected by the palpation exam (2016 personal communication with Dr. Paul Pinsky). Specificity ranged from 91 percent to 99 percent in the four studies. Calculated PPV ranged from 0 percent to 3.6 percent, and negative predictive value (NPV) was ≥99 percent for all studies. Accuracy estimates had wide confidence intervals due to the very low event rate.

Harms

Additional imaging and unnecessary surgical intervention are potential harms of pelvic examination screening for ovarian cancer. The prevalence of laparoscopy or laparotomy for those with abnormal findings on pelvic examination ranged from 5 to 36 percent. In the Greek study, 17 percent of the women with abnormal pelvic examination results underwent surgery due to the examination results. Pathology findings revealed two cases of ovarian cancer (one was metastatic and the other was a stage Ia serous cystadenocarcinoma), four serous cystadenomas, three mucinous cystadenomas, five endometroid cysts of the ovary, twelve benign cysts, and three normal pathology results. In the Australian study, two women (5%) with abnormal findings on pelvic examination had surgery. The surgeries revealed that one patient had a fibroid uterus and one a normal (negative) result; the single case of ovarian cancer was not detected on pelvic exam. In the United Kingdom study that recruited solely post-menopausal women, 36 percent of women with an abnormal pelvic examination result underwent surgery due to those results: one woman had ovarian cancer, and nine had benign conditions (six had benign ovarian cysts, one a fimbrial cyst, and two no identified pelvic pathology). In the PLCO trial, the surgery rate occurring subsequent to an abnormal ovarian palpation examination within one year of the abnormal screen was 11.2 percent (at the longest followup) with a complication rate (any complication: surgical, pulmonary, cardiovascular, infection, other) of 1.0 percent (Table 7). Further diagnostic procedures occurring subsequent to and within one year after an abnormal palpation screening test in the trial are reported in Table 7 (2016 personal communication with Dr. Paul Pinsky).
Bacterial Vaginosis

Summary of Findings

No screening studies were conducted solely in asymptomatic primary care populations. Two studies with large proportions of symptomatic patients had substantial clinical and methodological heterogeneity (populations, personnel performing index test, description of results of index tests, reference standards) and statistical heterogeneity (disparate accuracy results). These limitations hindered conclusions regarding the accuracy of the pelvic examination as a screening test for BV. Both included studies should be considered exploratory, hypothesis-generating investigations that cannot be used to estimate the accuracy of the pelvic examination as a screening test for BV in primary care populations.

Study Characteristics

We identified two fair-quality U.S. studies (n=930) that assessed the accuracy of different approaches to diagnosing BV, including pelvic examination. Gutman et al. recruited any woman undergoing a speculum examination from a hospital-based primary care clinic, colposcopy clinic, or research clinic, whereas Eschenbach et al. recruited nonpregnant women aged 16–50 years from an STI clinic. In the first study, personnel performing “routine pelvic examination” included second- through fourth-year obstetrician-gynecologists residents, research nurses, or an attending gynecologist, while the second study specified that a single “women’s health care specialist” perform a “standardized pelvic examination” with specific attention to the appearance of the vulva, vagina, and cervix; characteristics of vaginal discharge; and cervical, uterine and adnexal tenderness.

The Gutman study provided some details on patient characteristics and reported a mean age of 24.1 years with 38 percent of patients being white, 30 percent black, and 27 percent Hispanic. Thirty-three percent of patients in the Gutman study were symptomatic, while the STI clinic study reported 59 percent presenting with some pelvic or abdominal symptom as a chief complaint. Risk factors for BV were not reported for either study.

Neither study had a primary aim of estimating the accuracy of the pelvic exam; instead, they explored different clinical signs and diagnostic criteria for BV measured against a gold standard. The aim of the Gutman study was to report the diagnostic accuracy of using any two of Amsel’s criteria against the traditional diagnostic criteria of three of the four Amsel’s criteria (thin, homogeneous discharge; vaginal pH >4.5; positive whiff test or release of amine odor with potassium hydroxide; clue cells on saline wet prep microscopy). The aim of the Eschenbach study was to compare the observed findings on clinical pelvic examination against the gold-standard diagnostic criteria for BV. In the Gutman study, the index test included Amsel’s criteria with a score of three or greater; the reference test was a gram stain with a Nugent’s criteria score of seven or greater. The Eschenbach study used the index test of a standard pelvic examination reporting the accuracy of individually observed findings from a physical examination (homogeneous discharge, frothy discharge, increased discharge, yellow vaginal discharge, ectopy, adnexal tenderness) against the reference standard of pH and Gram stain.
microscopy. BV was diagnosed if the Gram stain revealed *Gardenerella*, one or more other bacterial morphologic types, and *Lactobacillus* (at quantities of ≤4 per oil immersion field).

**Yield and Accuracy**

Both studies reported a high prevalence of BV (39% and 47%).\(^{31, 32}\) Gutman et al.\(^{31}\) reported the sensitivity and specificity of thin, homogeneous discharge as 79 percent and 54 percent, respectively; PPV and NPV were calculated to be 52 percent and 80 percent, respectively (Table 9). Eschenbach et al.\(^{30}\) reported the sensitivity and specificity of homogeneous discharge as 69 percent and 97 percent, respectively (PPV 95% and NPV 79%).\(^{32}\) That study also reported the sensitivities for other individual pelvic examination findings, which ranged from 2 percent (frothy discharge) to 51 percent (ectopy), and specificity, which ranged from 48 percent (ectopy) to 100 percent (frothy discharge). PPV ranged from 42 percent to 100 percent and NPV ranged from 52 percent to 58 percent. Data reporting did not allow for calculations with strictly asymptomatic patients.

**Harms**

A possible harm of using pelvic examination to screen for BV is that the test could result in false-positive or -negative results, leading to unnecessary diagnostic workup for some women while others would not receive indicated treatment. In the Gutman study,\(^{31}\) the false-positive and -negative rates for the pelvic examination finding of thin homogeneous discharge were 46 percent and 21 percent, respectively. In the second study, the false-positive and false-negative rates for homogeneous discharge were 3 percent and 31 percent, respectively.\(^{32}\) Individual false-positive and -negative rates for other signs ranged from 0 to 52 percent and 49 to 98 percent, respectively.\(^{32}\)

**Genital Herpes (Herpes Simplex Virus-1 or -2)**

**Summary of Findings**

No screening studies were conducted solely in asymptomatic primary care populations. The single available study on the accuracy of pelvic examination to detect genital herpes recruited women from an STI clinic who were at high risk for the condition.\(^{33}\) Nonetheless, even in this higher STI prevalence population, 78 percent of women who had contracted any genital herpes at any time had asymptomatic shedding or latent disease which would not be detectable with a pelvic examination. In this single study, the pelvic examination finding of vulvar ulcerations had a sensitivity of 20 percent and specificity of 98 percent in detecting genital HSV at any stage.

**Study Characteristics**

One fair-quality trial by Koutsky et al. (n=779) assessed the accuracy of approaches to detect genital herpes infection and provided data on the accuracy of specific pelvic examination findings in detecting this condition.\(^{33}\) The study recruited nonpregnant women aged 16–50 years from the same population seen in the STI clinic for the BV study by Eschenbach\(^{32}\) and for the trichomoniasis study by Wolner-Hansson et al.\(^{34}\) (Table 8). All pelvic exams were performed by
one “women’s health care specialist.” Mean age was 24 years and 70 percent of participants were white. Almost all patients were sexually active (98%). Seven percent used condoms as the primary method of contraception and 33 percent did not use any contraception. Ten percent were symptomatic.

The index test was a “genital examination” with colposcopy (our report did not include lesions detected by colposcopy). A positive pelvic examination result was defined as clinician-detected lesions, but we could use reported data for only vulvar ulcerations and tender inguinal nodes in the accuracy calculations. All patients received the reference test, which included cultures from urine, cervical swabs, anal swabs, and any lesion swabs (all herpes simplex virus [HSV] isolates were confirmed and typed by direct immunofluorescence with use of mouse monoclonal antibodies) as well as serum testing for HSV-1 or HSV-2 antibodies using western blotting. The authors clearly defined cases as first episode (bilateral painful multiple vesicles, pustules, or ulcers on external genitalia, perineum, perianal area, or vaginal walls; cervical necrosis; or unilateral lesions plus constitutional symptoms without history of similar episodes, plus culture positivity and HSV-2 antibody negativity), recurrent episode (unilateral painful lesions on external genitalia, perineum, or perianal area; or bilateral small lesions and similar history or cervical ulcers without associated constitutional symptoms, plus culture or HSV-2 antibody positivity), asymptomatic viral shedding (no signs or symptoms, plus culture or antibody positivity), or latent subclinical infection (no signs or symptoms, plus HSV-2 antibodies present).

Yield and Accuracy

Nearly half (48%) of all study participants were diagnosed with genital herpes at some stage of the disease: 6 percent were diagnosed at the first episode, 5 percent had symptomatic recurrence, 2 percent had asymptomatic shedding, and 35 percent had latent HSV-2 infection (Table 9). Among patients at any stage of genital herpes, 22 percent were symptomatic on examination. We calculated the specificity and sensitivity of specific individual clinical findings as reported in the study (i.e., vulvar ulcerations, tender inguinal nodes) but were unable to use data on cervical ulcers because these numbers were aggregated to include cervical ulcers detected grossly with speculum examination as well as those found using a colposcope.

The presence of vulvar ulcerations had a sensitivity of 20 percent and specificity of 98 percent in detecting genital HSV at any stage (PPV, 88 percent; NPV, 57 percent). Similarly, the presence of tender inguinal lymphadenopathy had a sensitivity of 14 percent and specificity of 97 percent (PPV, 82 percent; NPV 55 percent). Data reporting did not allow calculations for strictly asymptomatic patients.

Harms

For the clinical finding of vulvar ulceration, the false-positive and false-negative rates were 2 percent and 80 percent, respectively, for any stage of genital herpes. For the clinical finding of tender lymphadenopathy, the false-positive and false-negative rates were 3 percent and 86 percent, respectively, for any stage of genital herpes.
Trichomoniasis

Summary of Findings

There were no screening studies conducted solely in asymptomatic primary care populations. One study of women with a high prevalence of symptoms (>50%) for *Trichomonas vaginalis* (trichomoniasis) who were recruited from an STI clinic provided an exploratory analysis of the accuracy of individual clinical examination findings showing <60 percent sensitivity for detecting trichomoniasis.34

Study Characteristics

The one study, a fair-quality trial by Wolner-Hanssen et al. (n=779), aimed to analyze the clinical manifestations of trichomoniasis and determined the accuracy of specific clinical findings on pelvic examination in detecting trichomoniasis.34 The study recruited nonpregnant women age 16–50 years from the same population seen in the STI clinic as the BV study by Eschenbach32 and the HSV study by Koutsky (Table 8).33 All pelvic examinations were performed by a single “women’s health care specialist.” Patient characteristics were described previously (Genital Herpes, Study Characteristics) from this random sample of STI clinic patients. At least half of the patients had vaginal symptoms: yellow discharge (23%), abnormal vaginal odor (36%), and vulvar itching (51%).

The index test was a standardized pelvic examination that included colposcopy. For the purposes of this report, we did not consider any findings from colposcopic examination. The definition of abnormalities was reported as increased vaginal fluid reported if the clinician noted moderate to markedly increased discharge compared with that seen in patients without genital infections. Saline preparation as well as Gram stain of vaginal samples were examined under a microscope at 100× and 400× magnification. All patients were specifically evaluated for colpitis macularis (“strawberry cervix,” defined as diffuse or patchy maculoerythematous lesions of the ectocervical epithelium). The reference test for identifying trichomoniasis was culture.

Yield and Accuracy

The prevalence of culture-confirmed trichomoniasis was 15 percent. For the most specific clinical sign, colpitis macularis (detected grossly, without a colposcope), we calculated the sensitivity as 2 percent and the specificity as 100 percent; PPV was calculated as 100 percent and NPV 85 percent (Table 9). For other individual clinical findings, sensitivity ranged from 8 to 59 percent and specificity from 72 to 99 percent: PPV ranged from 19 to 62 percent and NPV from 86 to 91 percent (Table 9). Data reporting did not provide sufficient information to calculate the sensitivity and specificity for the presence of any one or more abnormal findings on pelvic examination. Data reporting did not allow calculations with strictly asymptomatic patients.

Harms

Pelvic examination screening for trichomoniasis could result in missed cases whereby women do not receive indicated treatment. For the clinical findings of colpitis macularis, purulent
discharge, frothy discharge, vulvar erythema, and vaginal erythema, the false-positive rate ranged from 0 percent (colpitis macularis) to 28 percent (vulvar erythema). The false-negative rate ranged from 41 percent (purulent discharge) to 98 percent (colpitis macularis). The degree of harm from false-positive results is expected to be minimal given that the diagnostic test is benign and confirmation is conducted in the clinic, without delay, between a positive screening result and confirmation.

**Other Harms**

**Summary of Findings**

Beyond the false-positive rates and missed cases (described above) from accuracy studies, we identified one additional small fair-quality cohort study investigating a possible association between the pelvic examination and subsequent development of urinary symptoms. Further research is needed, in larger studies with urine culture-confirmed urinary tract infection (UTI) as the outcome, to confirm or disprove this potential harm.

**Characteristics of Included Studies**

In addition to the studies of harms related to the sensitivity and specificity estimates reported in diagnostic accuracy studies, we identified one study that considered the possibility of genitourinary infection being caused by routine pelvic examinations. In this 4-week prospective controlled cohort (n=150), sexually active women aged 18–40 years were seen in a university-based family medicine residency clinic. Subjects presented for a screening speculum exam, Pap test, and bimanual examination, while age-matched controls presented for other kinds of health maintenance visits. The study excluded women who had current or chronic urinary or vaginal symptoms, being treated with anti-infectives, with diabetes, or taking immunosuppressants. Outcomes were obtained through daily self-reported logs of urinary symptoms as well as medical chart review for a UTI diagnosis. Half of the enrolled patients (49%) dropped out before the end of the 4-week trial.

The average age of those completing the study was 26 years. The groups differed in two statistically significant ways: the control patients had intercourse more frequently and they used condoms more often than did the group that had undergone pelvic examination.

**Results**

UTI was diagnosed clinically (without culture) in only one subject in the pelvic examination group. Dysuria (11/63 versus 6/87; p<0.01) and urinary frequency (17/63 versus 12/87; p<0.01) were more common in the pelvic examination group during the 4-week followup. This study was limited in that there was high loss to followup, it was underpowered to detect a difference in UTI diagnoses between groups, and there were significant between-group differences in intercourse frequency and barrier use. This exploratory study cannot be used to make conclusions about the causality between pelvic examinations and UTIs.
Chapter 4. Discussion

We identified no literature that assessed the overall value of the pelvic examination in improving health outcomes for any medical conditions. Despite the many medical conditions that are plausibly detectable or that physicians cite as a rationale for routine screening pelvic exams, our review identified diagnostic accuracy studies for only one cancerous condition (ovarian cancer) and three infectious (BV, trichomoniasis, and HSV) conditions (Table 10).

Screening Accuracy

Ovarian Cancer

Our systematic review findings are consistent with other recent systematic reviews, but our review is the first to present unpublished data from the PLCO from over 20,000 screened women. (2016 personal communication with Dr. Paul Pinsky) All four studies included in our review recruited average-risk women so, unsurprisingly, the prevalence of ovarian cancer was quite low (0.04% to 0.1%) and the PPVs were also consistently low (<4%). These rare cases reflect the low incidence of ovarian cancer seen in U.S. women (0.01%, 11/100,000 women). The downstream consequences resulting from positive pelvic examination findings include surveillance with ultrasonography (one time or repeated) or other imaging and, in some cases, surgery. In our included studies, at one year, the prevalence of abnormal pelvic examination results ranged from 1.2 to 8.7 percent, and the prevalence of surgery of those women with abnormal findings ranged from 5 to 36 percent (2016 personal communication with Dr. Paul Pinsky). Due to advances in ultrasound technology since the publication of these studies, it could be hypothesized that the surgical intervention rate lies on the lower end of this range. In the only included US study, the large PLCO trial of almost all postmenopausal women, the ovarian palpation protocol occurred in the early to mid-1990’s, and reported a surgery rate of 11.2 percent within one year of an abnormal pelvic examination after 1 to 4 rounds of screening. There is no more recent evidence available to estimate the risk of surgical intervention resulting from screening pelvic examinations.

The PLCO trial used an even more sensitive screening procedure (transvaginal ultrasonography and CA-125) and found abnormal ultrasonography results in 5 percent of women (n=1338) who had received a baseline examination (n=28,519). Between the ultrasonography results and CA-125 levels, 6 percent of women required further assessment (n=1703) and 2 percent (n=570) underwent surgery (n=325 laparotomy; n=245 laparoscopy and/or vaginal approach). Ninety-eight percent of those women with abnormal screening results and 95 percent of those who underwent surgery were not diagnosed with ovarian cancer. As mentioned earlier, the PLCO trial originally included bimanual examination of the ovaries and rectovaginal examination in the screening protocol. The pelvic examination component was discontinued, however, because no ovarian cancers were detected solely with bimanual palpation. Notably, even the more sensitive screening tests (transvaginal ultrasonography and CA-125) were not found to significantly reduce rates of ovarian cancer-related mortality.
Cross-sectional studies showed that under the most optimal circumstances (patients preoperatively under anesthesia, all with some pelvic abnormality as indication for surgery, examination performed by attending physicians), the accuracy of the pelvic examination for detecting pelvic masses is low.\textsuperscript{40,41} Moreover, the accuracy of this examination to detect pelvic masses has been shown to be lower when performed by inexperienced trainee examiners, with obese patients, or with patients with an enlarged uterus.\textsuperscript{40-43} Our narrative synthesis of the limited available evidence suggests poor performance of the screening pelvic examination for detecting ovarian cancer.

**Infectious Diseases**

There were no diagnostic accuracy studies for infectious conditions in solely asymptomatic, average-risk populations. We did include four studies reporting diagnostic accuracy in high-risk settings (STI clinics or populations with high rates of symptoms), acknowledging that these studies likely overestimate accuracy characteristics when pelvic examinations are administered to average-risk, asymptomatic primary care populations. Again, even in these high-risk populations, the reported sensitivities are well below what would be considered minimal thresholds for clinically useful screening instruments.

**Harms**

Our review identified few studies on harms that met the inclusion criteria. The studies were largely the same studies from KQ2 (accuracy) on estimating indirect harms from false-positive results and missed cases, with an additional small cohort study by Tiemstra and colleagues\textsuperscript{35} on possible associations between pelvic examination and subsequent urinary symptoms. The potential downstream harms resulting from the diagnostic workup vary widely by gynecologic condition. For example, a false-positive result on pelvic examination for adnexal mass could result in ultrasonographic surveillance with or without diagnostic laparoscopy, while a false-positive finding on pelvic examination for abnormal vaginal discharge may result in the additional cost of a laboratory gram stain or NAAT or even unnecessary empiric antibiotic treatment. From a patient’s perspective and in the absence of empiric treatment, false-positive results associated with screening for trichomoniasis might have a modest impact given that the diagnostic testing and immediate confirmation or disconfirmation does not require an invasive test and little delay between the screening and diagnostic test results.

Another recent systematic review\textsuperscript{37} included 14 cross-sectional surveys\textsuperscript{44-57} and one cohort study\textsuperscript{58} addressing harms associated with pelvic examination and women’s attitudes about the exam; these studies were not included in our review because they did not meet the inclusion criteria. Exclusions were primarily due to their lack of generalizability and applicability to the U.S. primary care setting. The authors of that systematic review concluded that the pelvic examination may lead to pain, fear, anxiety, discomfort, or embarrassment in some proportion of women (range, 10% to 80%), but those data were of low quality. Additional cross-sectional literature suggests that certain populations of women—especially those with a history of sexual violence\textsuperscript{59-62} or abuse,\textsuperscript{63} chronic pelvic pain,\textsuperscript{64} or obesity\textsuperscript{65}—report more negative experiences from a pelvic examination and, as a result, may avoid seeking medical care.
Clinical Implications

Controversy surrounds the clinical implications of changes in screening periods for cervical cancer with respect to the role of annual screening pelvic examination.\(^4,66-70\) There are concerns that scrutiny of the accuracy of screening pelvic examination is misdirected, as the benefit of other routinely provided physical examination components (e.g., heart and lung auscultation screening) in the context of screening is similarly lacking.\(^67\) Rather than viewing the examination as a screening test, this perspective suggests that it is a point of contact with patients with broader clinical purpose, including to facilitate discussion of sensitive topics that would otherwise not be brought up.\(^70\) These concerns may echo physicians’ attitudes about the annual physical examination in general; one survey reported that most primary care physicians believe that an annual physical examination provides counseling time for preventive services, improves detection of subclinical disease, improves therapeutic relationships, and is desired by patients.\(^71,72\) Others are concerned that clinicians rely on ultrasonography so heavily that clinical acumen for the pelvic examination has declined; this concern has been cited as one reason for continued performance of routine pelvic examinations.\(^68,73\) On the other hand, the screening pelvic examination can cause anxiety and discomfort and could pose unnecessary barriers to care,\(^50\) especially in certain subpopulations of women (e.g., those with a history of sexual abuse\(^60-62\)). Notably, despite recommendations to the contrary,\(^64,75\) a survey reported that 79 percent of obstetrician-gynecologists thought at least one component of the pelvic examination was of some importance for determining contraception eligibility,\(^76\) and a survey from 2008–2009 found that nearly a third of obstetrician-gynecologists and family medicine physicians required the patient to undergo a pelvic examination before being prescribed oral contraceptives.\(^77\)

The fragmentation of preventive services in women’s health care is a well-recognized problem.\(^78,79\) Women’s preventive care is provided by clinicians with diverse training and professional orientations, and women seek care from different types of providers over the lifespan, resulting in variability in the comprehensiveness of primary care.\(^80-82\) It is uncertain if changes to routine screening pelvic examination practices will affect women’s patterns of health care use and their receipt of comprehensive primary and preventive health care at different stages of life.

Limitations

Our systematic review captured all of the English-language published literature on the screening accuracy of the pelvic examination in asymptomatic, average-risk populations. In our initial abstract review, we conservatively included studies that could possibly meet the inclusion criteria for full-text review. In almost all cases, these studies did not meet inclusion criteria on full-text review. We specifically excluded studies recruiting participants at high risk for ovarian cancer (e.g., symptoms, known masses, those with a family history of ovarian cancer)\(^83-86\) or those reporting incomplete data regarding accuracy\(^87,88\); these studies are summarized elsewhere.\(^36\) We included STI accuracy studies in settings outside of primary care but these studies probably included some average-risk patients, thus providing data on accuracy which should be cautiously interpreted for average-risk primary care populations. In addition, our study design inclusion criteria excluded several qualitative studies and survey studies on the harms of
pelvic examination (including discomfort and anxiety), but we do not believe that those studies added precision to the estimation of screening harms.\textsuperscript{44-57}

The aim of the conceptual framework presented in our report was to define the potential yield as well as the presence of well-established, evidence-based alternative screening tests for conditions like cervical cancer, gonorrhea, and chlamydia.\textsuperscript{89, 90} We acknowledge that no studies examined the yield of the pelvic examination in detecting any treatable pelvic pathology. In other words, while the sensitivity of the pelvic examination was low for detecting a single condition (e.g., ovarian cancer or BV), on the basis of current evidence we could not estimate the value of the screening pelvic examination to detect any condition in the list of possible disease conditions prior to the clinical presentation with symptoms. Epidemiologic evidence for estimating the burden of single conditions, biologic plausibility of early detection using the pelvic examination, treatability of the disease at earlier stages, and alternative, superior screening approaches are considerations for clinical guidance as there is no literature available to estimate the potential cumulative benefits or harms of screening pelvic exam.

This systematic review did not evaluate the role of history taking in eliciting symptoms in patients who do not present with gynecologic-related chief complaints but do affirm one or more gynecological symptoms on review of body systems. This topic was not considered in the scope of this systematic review since it was aimed at determining the effectiveness of routine screening pelvic examinations in average-risk, asymptomatic women in primary care settings. We did perform a targeted search of this approach to case finding and found no relevant literature. Furthermore, studies examining the accuracy of the pelvic examination as a diagnostic tool for symptomatic patients (e.g., patients presenting with symptoms of pelvic pain, vaginal discharge, or dyspareunia) were outside the scope of this review. Pelvic examination remains an important tool in diagnosing pelvic pathology for symptomatic patients.\textsuperscript{20}

**Research Gaps**

We found no studies examining the effect of the pelvic examination on morbidity, mortality, or quality of life. Further, we identified no in-progress studies examining the effectiveness or screening accuracy of the pelvic examination for any condition. Given the inconsistent guidelines and limited evidence, trials randomizing women to different pelvic screening examination protocols could provide estimates of the benefits and harms for women at different stages of life. In light of the limited evidence on the clinical benefits or harms of routine pelvic examination for preventive screening, research questions related to improvements to women’s primary health care delivery warrant consideration. In the face of changing clinical practice with respect to cervical cancer screening frequency and new recommendations from professional organizations,\textsuperscript{9, 20} it remains unclear if altering the schedule for routine pelvic examinations will influence the uptake of other evidence-based preventive services (e.g., blood pressure screening, obesity screening). Similarly, there is no literature on the opportunity costs the pelvic examination could pose for the receipt of other recommended preventive services. These changes and others would be important to study given the longstanding patterns of women’s primary health care delivery. Also needed are investigations that compare strategies for implementing
patient-centered approaches to preventive screening along with provider- and patient-focused strategies to continue improving the delivery of evidence-based prevention.

Further research into the primary care gaps and coordination issues that women face in obtaining comprehensive primary care might help to clarify optimal patterns of health care use from the patient’s perspective as well as from public health and clinical standpoints. It remains unclear what components of physical examination in routine primary care visits are most important for maintaining health and whether women’s patterns of health care use would change if routine pelvic examinations were not recommended per American College of Physicians guidelines or were based on shared decisionmaking conversations, as suggested in the recent WWTF guidelines. Changes to routine practices of pelvic examination could either improve or worsen the comprehensiveness and continuity of primary care for women; the effects could also depend on a woman’s age or overall health. Patients’ expectations and preferences for pelvic examination also warrant further investigation, as the current guidance on screening pelvic examinations from ACOG and WWTF suggest a shared decisionmaking paradigm wherein these personal perspectives would inform practices. Regardless of the need for targeted preventive screening services, some women may wish to have an annual gynecological visit.

Conclusions

No studies have provided evidence of the health benefits—and limited evidence on the accuracy of the screening pelvic examination—for gynecologic conditions that might be detected. Although lack of evidence is not conclusive evidence of no benefit, the existing evidence highlights the limited sensitivity of screening pelvic examination in detecting ovarian cancer and select infections. Asymptomatic conditions that might be detected during a routine pelvic examination and treated to improve a patient’s health have not been fully outlined and evaluated for test accuracy. Nor has there been sufficient evidence to fully evaluate the potential harms of the exam. Furthermore, no studies have examined the health outcomes for screened and unscreened populations to provide overarching evidence of the overall benefits and harms of the screening pelvic examination across all potential health conditions prevented.

Mortality rate: 0.2/100,000*<sup>38</sup> | Vaginal discharge; abnormal bleeding; change in bathroom habits; pelvic or abdominal pain, dysuria, dyspareunia<sup>96</sup> | Gross vaginal lesions on internal speculum exam |
| Vulvar             | All ages, but mostly women aged 75–84 years<sup>97</sup> | Incidence rate: 2.6/100,000*<sup>38</sup>  
Mortality rate: 0.5/100,000*<sup>38</sup> | Itching, burning, or bleeding on the vulva; changes in vulva skin color or appearance; sores, lumps, or ulcers on vulva; pelvic pain, dysuria, dyspareunia<sup>96</sup> | Gross vulvar lesions on external examination |
| **Infectious diseases** |                                                           |                                          |                                                                  |                                                         |
| Bacterial vaginosis| All ages, most commonly women aged 15–44 years<sup>98</sup> | Most common vaginal infection 15–44 years<sup>98</sup>  
Prevalence: 29.2% (14–49 years)<sup>99</sup> | Often asymptomatic<sup>98</sup> | Asymptomatic discharge on internal speculum exam |
| Candidiasis        | All ages; those who have diabetes, are pregnant, have long-term use of broad-spectrum antibiotics, or use corticosteroid medications at higher risk<sup>100</sup> | Nearly 75% of adult women have had ≥1 candidiasis occurrence<sup>100</sup>  
Between 29% and 49% of premenopausal women had ≥1 lifetime episode<sup>101</sup> | Symptomatic vaginal discharge, pruritus | Vaginal discharge detected on internal speculum exam |
| Genital warts (HPV)| All ages                                                  | 120 incident cases/100,000 women each year<sup>102</sup>  
Lifetime history of anogenital warts: 7.2%<sup>102</sup> | Asymptomatic or symptomatic, depending on location and size of warts | Gross lesions on external or internal speculum exam |
| Herpes (HSV-1, HSV-2)| All ages                                                 | 20.9% (HSV-2) among females 14–49 years old<sup>103</sup>  
52.3% (HSV-1) among women aged 20–29 years, 33.2% among women aged 14–19 years<sup>104</sup> | Asymptomatic or primary/secondary disease with typical labial ulcerative lesions | Gross ulcerative lesions on external or internal speculum exam |

## Table 2. Recommendations on the Periodic Pelvic Examination for Asymptomatic Adult Women

<table>
<thead>
<tr>
<th>Group or Professional Society</th>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>AAFP[19]</td>
<td>Screening pelvic examination in asymptomatic, nonpregnant, adult women is not recommended. [Based on the ACP recommendation]</td>
</tr>
<tr>
<td>ACOG[10]</td>
<td>No evidence supports the routine internal examination of the healthy, asymptomatic patient before age 21 years. Recommends that a pelvic examination be performed in all patients aged 21 years and older. No evidence supports or refutes the annual pelvic examination or speculum and bimanual examination for the asymptomatic, low-risk patient. The decision whether or not to perform a complete pelvic examination at the time of the periodic health examination for the asymptomatic patient should be a shared decision after a discussion between the patient and her health care provider.</td>
</tr>
<tr>
<td>WWTF[20]</td>
<td>For patients 21 years and older, recommends speculum and/or bimanual examination for asymptomatic patients with specific indications (e.g., intrauterine device placement, cervical cancer screening). External examinations may be performed annually in healthy patients. The inclusion of speculum, bimanual examination, or both in otherwise well women should evolve from informed decisionmaking between patient and provider. (Qualified) [Based on the ACOG recommendation.]</td>

A = Strongly Recommended: The USPSTF strongly recommends that clinicians provide [the service] to eligible patients. The USPSTF found good evidence that [the service] improves important health outcomes and concludes that benefits substantially outweigh harms.

B = Recommended: The USPSTF recommends that clinicians provide [the service] to eligible patients. The USPSTF found at least fair evidence that [the service] improves important health outcomes and concludes that benefits outweigh harms.

C = No Recommendation: The USPSTF makes no recommendation for or against routine provision of [the service]. The USPSTF found at least fair evidence that [the service] can improve health outcomes but concludes that the balance of benefits and harms is too close to justify a general recommendation.

D = Not Recommended: The USPSTF recommends against routinely providing [the service] to asymptomatic patients. The USPSTF found at least fair evidence that [the service] is ineffective or that harms outweigh benefits.

I = Insufficient Evidence to Make a Recommendation: The USPSTF concludes that the evidence is insufficient to recommend for or against routinely providing [the service]. Evidence that the [service] is effective is lacking, of poor quality, or conflicting and the balance of benefits and harms

### Appendix A Table 2. Quality Assessment Criteria

<table>
<thead>
<tr>
<th>Study Design</th>
<th>Adapted Quality Criteria</th>
<th>USPSTF Ratings</th>
</tr>
</thead>
</table>
| **Observational studies (e.g., prospective cohort studies), adapted from the Newcastle-Ottawa Scale (NOS)** | • Was there representativeness of the exposed cohort?  
• Was the nonexposed cohort systematically selected?  
• Was the ascertainment of exposure reported?  
• Was the outcome of interest not present at baseline?  
• Were measurements equal, valid, and reliable?  
• Were outcome assessors blinded?  
• Was followup long enough for the outcome to occur?  
• Was there acceptable followup? | **Good:** Meets all criteria: Comparable groups are assembled initially and maintained throughout the study (follow-up at least 80 percent); reliable and valid measurement instruments are used and applied equally to the groups; interventions are spelled out clearly; all important outcomes are considered; and appropriate attention to confounders in analysis. *Fair:* Studies will be graded “fair” if any or all of the following problems occur, without the fatal flaws noted in the “poor” category below: Generally comparable groups are assembled initially but some question remains whether some (although not major) differences occurred with follow-up; measurement instruments are acceptable (although not the best) and generally applied equally; some but not all important outcomes are considered; and some but not all potential confounders are accounted for. *Poor:* Studies will be graded “poor” if any of the following fatal flaws exists: Groups assembled initially are not close to being comparable or maintained throughout the study; unreliable or invalid measurement instruments are used or not applied at all equally among groups (including not masking outcome assessment); and key confounders are given little or no attention. |

| **Diagnostic accuracy studies, adapted from the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) I and II instrument** | • Could the selection of patients have introduced bias?  
  o Was the spectrum of patients representative of the patients who will receive the test in PC?  
  o Was the selection process clearly defined?  
  o Are there concerns that the included patients and setting do not match the review question?  
• Could the conduct or interpretation of the index test have introduced bias?  
  o Was the index test interpreted without knowledge of the reference standard results?  
  o If a threshold was used, was it prespecified?  
  o Are there concerns that the index test, its conduct, or its interpretation differ from the review question?  
• Could the conduct or interpretation of the reference standard have introduced bias?  
  o Is the reference standard likely to correctly classify the target condition?  
  o Was the reference standard interpreted without knowledge of the index test results?  
  o Are there concerns that the target condition as defined by the reference standard does not match the review question?  
  o Did the whole or partial selection of patients receive the reference standard?  
• Could the patient flow have introduced bias?  
  o Was there an appropriate interval between the index test and reference standard?  
  o Did all patients receive the same reference standard?  
  o Were all patients included in the analysis? | **Good:** Evaluates relevant available screening test; uses a credible reference standard; interprets reference standard independently of screening test; reliability of test assessed; has few or handles indeterminate results in a reasonable manner; includes large number (more than 100) broad-spectrum patients with and without disease. *Fair:* Evaluates relevant available screening test; uses reasonable although not best standard; interprets reference standard independent of screening test; moderate sample size (50 to 100 subjects) and a “medium” spectrum of patients. *Poor:* Has fatal flaw such as: Uses inappropriate reference standard; screening test improperly administered; biased ascertainment of reference standard; very small sample size or very narrow selected spectrum of patients. |

Note: All studies were classified as good, fair, or poor according to the USPSTF Procedure Manual.\(^{23}\)
