Behavioral Interventions and Counseling to Prevent Child Abuse and Neglect: A Systematic Review to Update the U.S. Preventive Services Task Force Recommendation

Shelley S. Selph, MD; Christina Bougatsos, MPH; Ian Blazina, MPH; and Heidi D. Nelson, MD, MPH

Background: In 2004, the U.S. Preventive Services Task Force (USPSTF) found, on the basis of the results of a previous review (1, 2), insufficient evidence to recommend for or against routine screening of parents or caregivers for abuse or neglect of children (3, 4). This systematic review is an update for the USPSTF that focuses on studies published since the previous recommendation and addresses the effectiveness and adverse effects of behavioral interventions and counseling to prevent child abuse and neglect for children at potentially increased risk. Separate reviews examine screening women for intimate partner violence (5, 6) and elder abuse and neglect in vulnerable adults (6).

Data Sources: MEDLINE and PsycINFO (January 2002 to June 2012), Cochrane Central Register of Controlled Trials and Cochrane Database of Systematic Reviews (through the second quarter of 2012), Scopus, and reference lists.

Study Selection: English-language trials of the effectiveness of behavioral interventions and counseling and studies of any design about adverse effects.

Data Extraction: Investigators extracted data about study populations, designs, and outcomes and rated study quality using established criteria.

Data Synthesis: Eleven fair-quality randomized trials of interventions and no studies of adverse effects met inclusion criteria. A trial of risk assessment and interventions for abuse and neglect in pediatric clinics for families with children aged 5 years or younger indicated reduced physical assault, Child Protective Services (CPS) reports, nonadherence to medical care, and immunization delay among screened children. Ten trials of early childhood home visitation reported reduced CPS reports, emergency department visits, hospitalizations, and self-reports of abuse and improved adherence to immunizations and well-child care, although results were inconsistent.

Limitation: Trials were limited by heterogeneity, low adherence, high loss to follow-up, and lack of standardized measures.

Conclusion: Risk assessment and behavioral interventions in pediatric clinics reduced abuse and neglect outcomes for young children. Early childhood home visitation also reduced abuse and neglect, but results were inconsistent. Additional research on interventions to prevent child abuse and neglect is needed.

Primary Funding Source: Agency for Healthcare Research and Quality.

In 2004, the U.S. Preventive Services Task Force (USPSTF) found, on the basis of the results of a previous review (1, 2), insufficient evidence to recommend for or against routine screening of parents or caregivers for abuse or neglect of children (3, 4). This systematic review is an update for the USPSTF that focuses on studies published since the previous recommendation and addresses the effectiveness and adverse effects of behavioral interventions and counseling to prevent child abuse and neglect for children at potentially increased risk. Separate reviews examine screening women for intimate partner violence (5, 6) and elderly and vulnerable adults for abuse (6).

Approximately 695,000 children in the United States were victims of child abuse and neglect in 2010, and 1537 died (7). Most of these deaths were in infants and toddlers (7). Additional immediate health consequences of abuse and neglect include injuries and emotional and behavioral problems (8, 9). Associated long-term physical conditions include neurologic and musculoskeletal disorders; gastrointestinal problems; metabolic conditions, including diabetes; autoimmune disorders (10, 11); obesity (12, 13); chronic pain (14, 15); teen pregnancy and pregnancy complications (16); and others (17). Chronic mental health conditions include psychosis, anxiety and posttraumatic stress disorder, alcohol and substance abuse, risky sexual behaviors, depression and suicide, eating disorders, attention problems, and personality disorders (12, 18–25).

In the United States, child abuse and neglect have legal as well as medical implications. Federal legislation defines child abuse and neglect as any recent act or failure to act on the part of a parent or caregiver that results in death, serious physical or emotional harm, sexual abuse, or exploitation, or an act or failure to act that presents an imminent risk for serious harm (26–28). Although laws vary, states are required to include the minimum standards of the federal law (29). All states have laws that require physicians and other health care workers, as well as other professionals who interact with children, to report suspected child abuse and neglect to Child Protective Services (CPS) (30), part of the larger U.S. Department of Health and Human Services that specifically responds to child abuse reports (28).

Web-Only
CME quiz (preview on page I-22)
Physicians and other health care providers who care for children and families are uniquely situated to identify children at risk for abuse and neglect during well-child and other visits and to initiate interventions to prevent harm. Although pediatricians consider screening for abuse and neglect one of their important roles (31), it is rarely done in practice (32, 33). Barriers to screening include lack of experience, training, and confidence in handling abuse cases (32, 34–36).

METHODS

We developed and followed a standard protocol. A technical report that includes additional methods, search strategies, evidence tables, and descriptions of earlier trials is available at www.uspreventiveservicestaskforce.org (37). The USPSTF and Agency for Healthcare Research and Quality (AHRQ) determined the key questions for this update by using the methods of the USPSTF (38). Investigators created an analytic framework incorporating the key questions and outlining the patient population, interventions, outcomes, and potential adverse effects (Appendix Figure 1, available at www.annals.org).

The target population includes children from birth to age 18 years and their caregivers who interact with health care providers in clinical settings where primary care is delivered to children. This review does not include studies of children with signs, symptoms, or complaints of abuse or neglect because those findings would elicit evaluation outside the scope of primary prevention recommendations. Outcomes included in this review incorporate currently accepted definitions of child abuse and neglect, an understanding of a continuum of potential outcomes, and an acknowledgment that only some outcomes are actually measurable in research studies. Intermediate outcomes, such as referral rates, use of counseling services, or measures of parent-child bonding, are outside the scope of this review. Main outcomes include measures of reduced exposure to abuse and neglect (CPS reports, removal of the child from the home, and caregiver self-reports of abuse or assault), measures of health outcomes related to abuse (physical injuries, death, emergency department visits, and hospitalizations), and measures of child neglect (adherence with immunizations and well-child visits).

Search Strategies

In conjunction with a research librarian, we used the National Library of Medicine’s Medical Subject Headings keyword nomenclature to search the Cochrane Central Register of Controlled Trials and Cochrane Database of Systematic Reviews through the second quarter of 2012 and MEDLINE and PsycINFO from January 2002 to June 2012 for relevant English-language studies, systematic reviews, and meta-analyses. We also reviewed reference lists of papers and, using Scopus, reviewed citations of key studies.

Study Selection

Investigators developed inclusion and exclusion criteria for abstracts and articles based on the target population, key questions, and outcome measures. We included research that was done in the United States or in similar populations that receive services and interventions applicable to medical practice in the United States and was published in 2003 or later. After an initial review of abstracts, investigators reviewed full-text articles and conducted a second review to ensure eligibility. Appendix Figure 2 (available at www.annals.org) shows the search and selection diagram.

We included trials of the effectiveness of behavioral interventions and counseling to reduce exposure to abuse or neglect or improve health outcomes. Studies were eligible for inclusion if they enrolled children without obvious signs or symptoms of abuse or neglect, used a method to identify families or children at risk that was applicable to primary care, evaluated an intervention that primary care clinicians could access or provide referral for, measured outcomes related to abuse or neglect, and compared outcomes between intervention and nonintervention groups. We included all types of CPS reports (confirmed and unconfirmed) because research indicates no association between substantiation status and behavioral and developmental outcomes (39). We excluded studies focused on clinician education, methods to increase screening rates, and perceptions and attitudes of physicians and other clinicians, as well as studies of public awareness campaigns or other interventions not applicable to primary care settings and studies of interventions directed at perpetrators. Studies of any design were included to describe potential adverse effects of behavioral interventions and counseling. Potential adverse effects include escalating levels of abuse and neglect; false-positive evaluations; adverse consequences as a result of the investigation process; labeling, stigmatizing, and psychological distress; dissolution of families; and legal issues.

Data Abstraction and Quality Rating

An investigator abstracted data about study design and setting; participant characteristics; data collection procedures; numbers enrolled and lost to follow-up; methods of exposure and outcome ascertainment; analytic methods, including adjustment for confounders; and outcomes. A second investigator confirmed the accuracy of data.

We used criteria developed by the USPSTF to assess the quality of studies (38, 40). We assessed the applicability of studies by using the PICOTS (population, intervention, comparator, outcomes, timing of outcomes measurement, and setting) framework adapted to this topic (41). Two investigators independently rated the quality and
applicability of each eligible study as good, fair, or poor. Final ratings were determined by consensus.

Data Synthesis

We assessed the aggregate quality of the body of evidence for each key question as good, fair, or poor by using methods developed by the USPSTF based on the number, quality, size, and applicability of studies and the consistency of results between studies (38). Studies were considered consistent if outcomes were generally in the same direction of effect and ranges of effect sizes were narrow. Consistency was determined by consensus of the investigators.

External Review

The draft report was reviewed by content experts, USPSTF members, AHRQ program officers, and collaborative partners.

Role of the Funding Source

The study was funded by AHRQ under a contract to support the work of the USPSTF. Staff at AHRQ and members of the USPSTF developed the scope of the work. Approval from AHRQ was required before the manuscript could be submitted for publication, but the authors are solely responsible for its content and the decision to submit it for publication.

RESULTS

Key Question 1

For children without obvious signs and symptoms of abuse or neglect but potentially at increased risk, how well do interventions and counseling initiated in primary care settings reduce exposure to abuse or neglect, physical or mental harms, or mortality?

Eleven randomized trials evaluating the effectiveness of child abuse and neglect prevention interventions met inclusion criteria for this update (Table 1) (42–52). One trial evaluated a clinic-based intervention (44), and 10 trials evaluated early childhood home visitation, including the Healthy Start (43, 46), Early Start (49), Healthy Families (45, 47), Child First (51), and Family Partnership Model (42) programs; long-term follow-up of an early home visitation trial based in Memphis, Tennessee (52); and 2 other home visitation interventions (48, 50). All studies were rated fair-quality, rather than good-quality, because of specific methodological limitations or lack of information about methods. These included inadequate inclusion and exclusion criteria (42), randomization or allocation concealment (42, 43, 45, 47, 49–51, 53), or blinding (43, 48, 49); low adherence with the intervention (≤50%) (45, 47, 53); high loss to follow-up (>20%) (43–45, 48–51); dissimilar groups at baseline or follow-up (44, 47, 50, 51, 53); and lack of intention-to-treat analysis (42–45, 47–53).

All trials enrolled participants from primary care or maternity practices or settings. Although enrollment criteria for the trials varied, most included risk factors related to the child or parents (Table 2). Some trials used formal risk assessment instruments, such as the Kempe Family Stress Checklist (45–47), Parent Screening Questionnaire (44), or Parent Risk Questionnaire (51), as either a primary or secondary step in determining risk.

Clinic-Based Interventions

A trial based in a pediatric clinic compared outcomes of children whose parents had risk assessment followed by physician and clinic-based social work interventions, as needed, with outcomes of children receiving usual primary care (44). The trial was based on the Safe Environment for Every Kid (SEEK) model, which includes risk assessment during the course of usual primary care services, training physicians in addressing risk factors for abuse and neglect, providing informational resources for parents and physicians, and providing social work services to families desiring them. Outcome measures were obtained from CPS reports, children’s medical charts, and parent responses on the Parent–Child Conflict Tactics Scale. Outcome data were collected at baseline and 3 years later.

The trial enrolled 729 participants from university-based, pediatric primary care resident continuity clinics serving low-income families in Baltimore, Maryland. Children were newborn to age 5 years, and most were African American with single mothers receiving Medicaid or aid from State Children’s Health Insurance Programs. Clinics were randomly assigned in clusters to either the SEEK model or usual care on the basis of clinic day of the week. The usual care control group received standard pediatric care and services from an onsite human services worker with similar responsibilities as the social worker for the intervention group. For the intervention group, risk factor assessment was conducted using the Parent Screening Questionnaire, a 20-item, self-report questionnaire of safety issues that examines major risk factors for child abuse and neglect, such as parental depression and substance abuse. For participants with positive responses, trained physicians addressed concerns and provided educational materials, treatment, and referrals as needed. A social worker provided clinic-based interventions on a case-by-case basis (Dubowitz H. Personal communication.) (44).

Results indicated that, although 12% of families in both groups were involved with CPS before the trial, families in the intervention group had fewer CPS reports than did those in the usual care group as long as 44 months after the intervention (13% vs. 19%; \(P = 0.03\)) (Table 3). These findings represented all CPS reports, except for cases where abuse or neglect were explicitly ruled out. Also, parents in the intervention group reported fewer episodes of severe or very severe physical assault (average weighted Parent–Child Conflict Tactics Scale score, 0.11 vs. 0.33; \(P = 0.04\)), fewer instances of nonadherence to medical

care (5% vs. 8%; P = 0.05), and fewer delays in immunizations (3% vs. 10%; P = 0.002) than did parents in the usual care group.

Seventy-six percent of enrolled participants completed the study protocol. Factors that could have reduced differences between groups include diffusion of the SEEK model to the control group clinics when physicians changed clinic days or communicated with colleagues; similarity of services for intervention and control groups; and surveillance bias that increased detection of abuse and neglect, even in the absence of formal risk assessment. Applicability of the trial was limited by its being conducted in only 1 pediatric clinic setting serving a narrowly defined population but was enhanced by its use of existing health care services.

within primary care practices to integrate risk assessment into usual health care processes.

Home Visitation Interventions

Ten randomized trials evaluated the effectiveness of early childhood home visitation interventions to prevent child abuse and neglect and enrolled participants on the basis of risk assessment (42, 43, 45–52). Most trials were modeled after nurse home visitation interventions initiated more than 15 years ago in Elmira, New York (54), and Memphis, Tennessee (55). The primary intervention included visits to the participant’s home by either a paraprofessional, such as a layperson who completed a 9-week training course, or by a professional, typically a nurse. Home visits occurred postnatally or both prenatally and postnatally for 3 to 36 months after birth. Although the trials used the same basic approach, they differed in enrollment criteria, duration of intervention and follow-up, type of provider, outcome measures, and other important factors (45, 46, 48, 50). Outcomes of trials reporting at least 50% adherence to the interventions, including death, CPS reports, and health care measures, are summarized in Table 3.

In a long-term follow-up study of the Memphis trial that included 743 children, those receiving home visits from a nurse as infants were less likely to die by age 9 years than those in the usual care control group, although results were of borderline statistical significance (1 vs. 10 deaths; \( P = 0.08 \)) (52). In this study, the 1 death in the home visit group was the result of chromosomal abnormalities; of the 10 children who died in the control group, 3 died from complications of prematurity, 3 from the sudden infant death syndrome, 3 from injury (homicide by firearm, accidental injury from firearm, and motor vehicle accident), and 1 from an intestinal infection.

Five randomized, controlled trials provided CPS reports as an outcome, including confirmed CPS reports (45–47), all types of CPS reports (51), and parent descriptions of CPS reports (49). No trials found differences in rates of CPS reports between home-visited children and control children while the studies were ongoing (45–47, 49, 51). However, 1 trial found that children visited by a professional clinical team had decreased CPS involvement at 3 years after enrollment (odds ratio for effect of the intervention, 2.1 [95% CI, 1.0 to 4.4]) (51), whereas 2 others found no differences after 18 months (42) or 36 months (46). Two trials indicated that home-visited children were not removed from their homes at statistically significantly higher rates than control children (42, 46).

Three trials evaluated hospital emergency department visits by enrolled children (45, 49, 50). A trial specifically evaluating visits for injuries or ingestions reported reduced hospital visits for home-visited children (odds ratio, 0.59 [CI, 0.36 to 0.98]) (49). Two other trials reported no differences in emergency department visits for ambulatory

† $P < 0.05$ for all periods (4, 6, 9, and 12 mo).

Care–sensitive conditions (visits that might have been prevented if timely and appropriate care had been provided) (45) or for all types of indications (50).

Five trials reported no statistically significant effects of home visitation on the number or percentage of children hospitalized in general (42, 50), because of child abuse and neglect (49), or for ambulatory care–sensitive conditions (45, 46). A trial with a 12-month nurse visitation intervention and an additional 12-month follow-up found that nurse-visited children had fewer episodes of hospitalizations for all indications (19 vs. 36; $P < 0.01$) and fewer mean hospitalization days (143 vs. 211; $P < 0.001$) at 24 months than control children (50).

Three trials included measures of potential medical neglect, including nonadherence to recommended immunizations, well-child visits, or both (48–50). In 1 trial, home-visited children received immunizations at an earlier age than control children, resulting in significant differences between groups through age 9 months (2.20 vs. 1.64 mean visits; $P = 0.01$) but not at 12 months (48). Other trials indicated no differences in the second year with 24-month-old children (50) or in the third year (49). A trial reporting significant differences in the mean number of well-child visits at 9 months (3.14 vs. 2.18 mean visits; $P = 0.0098$) and 12 months (3.51 vs. 2.68 mean visits; $P = 0.0098$) also found that the more contact the children had with study personnel the more well-child visits they had at 12 months ($P = 0.036$) (48). In another trial, home-visited children were more likely to be up to date with well-child visits (42% vs. 30%; $P < 0.05$) and enrolled for dental care (72% vs. 63%; $P < 0.05$) over a 36-month period than children who were not in the program (49).

Studies using self-reported measures of abuse and neglect are subject to biased reporting, particularly because acknowledgment of child abuse and neglect is reportable to CPS. Five trials used the Parent–Child subscale of the Conflict Tactics Scale to assess mothers’ self-reports of abusive and neglectful behaviors toward their children (43, 45–47, 49). One trial found a significant difference in self-reported severe physical assault at 36 months (4%) of home-visited mothers vs. 12% of control mothers; $P < 0.01$) (49). Although another trial indicated no differences in the prevalence of abuse or neglect at 24 months, home-visited mothers reported one fourth as many acts of serious physical abuse, such as kicking or punching the child, compared with control mothers ($P = 0.03$) (47). Two other trials reported no differences in child maltreatment between groups (45, 46). In a trial comparing a cognitive-based extension of the Healthy Start home visitation program with the usual Healthy Start program, there were few instances of self-reported abuse on the Conflict Tactics Scale (43), although the prevalence of spanking or slapping
was lower in the enhanced group than in the unenhanced group (21% vs. 35%; \( P = 0.03 \)).

**Key Question 2**

What are the adverse effects of behavioral interventions and counseling to reduce harm from abuse and neglect?

Adverse effects of interventions were not explicitly evaluated in the trials, and additional studies of adverse effects were not identified by the literature searches. Although not described in the publication, during the SEEK trial, investigators maintained regular contact with the pediatric primary care practices involved in the trial and actively monitored potential adverse effects. No adverse effects were reported by participants (Dubowitz H. Personal communication.).

**DISCUSSION**

Table 4 summarizes the evidence reviewed for this update. A trial of risk assessment and behavioral interventions and counseling in a pediatric clinic showed statistically significantly reduced measures of abuse and neglect for young children and observed no adverse effects from the interventions. Outcomes included reduced physical assault, CPS reports, medical care nonadherence, and immunization delay. This trial is, to our knowledge, the first to determine the effectiveness of a clinic-based intervention in preventing child abuse and neglect, and it demonstrated the feasibility of the SEEK model by integrating it into usual care processes of the clinic. The applicability of these results was limited by the enrollment of participants from only a single clinical site with a narrowly defined high-risk population. A second trial using the SEEK model included 66 pediatricians and 24 nurse practitioners in 18 private practices in mostly suburban areas with primarily white, middle-class patients (56). Mothers in the SEEK practices reported less psychological aggression and minor physical assault than did mothers in usual care practices (56); however, additional outcomes have not yet been published (57).

Ten trials of early childhood home visitation indicated reduced death, CPS reports, emergency department visits, hospitalizations, and self-reports of abuse and neglect and improved adherence to immunizations and well-child care. However, some results were of borderline statistical significance or were inconsistent across trials. Although adverse effects of home visitation were not specifically stated, 2 trials indicated that home-visited children were not removed from their homes at statistically significantly higher rates than were control children (42, 46). These recent trials provide new information about the effectiveness of home visitation on long-term mortality, adherence with immunizations and well-child visits, and self-reported abuse and neglect.

The new trials also build on research considered in the previous USPSTF review (1, 2) and support findings of earlier trials (37). Although most trials indicated that home-visited children did not have fewer CPS reports than did usual care children during the course of the trial, CPS reports were statistically significantly reduced after 3 years of follow-up in a recent trial of the Child First program (51) and after 15 years of follow-up in the previously published Elmira trial (58). Also, recent trials showing reduced use of health care services for home-visited children, such as emergency department visits (49, 50) or hospitalizations

Behavioral Interventions and Counseling to Prevent Child Abuse and Neglect

Abuse. Elevations in serum or cerebrospinal fluid levels of neuron-specific enolase and myelin-basic protein, for example, provide measures of inflicted traumatic brain injury in otherwise normal-appearing infants (69, 70). Use of pancreatic and liver enzymes to screen for occult abdominal trauma in situations of possible physical abuse has also been explored (71).

Approaches applicable to children of all ages need to be developed, validated, and tested. The lack of studies assessing older children, identified in the previous USPSTF review as an important evidence gap, has yet to be addressed. Efforts to improve identification of children at risk for abuse and neglect need to be coupled with development and evaluation of effective interventions to which they can be referred once identified. Additional research on the effectiveness of interventions is needed to support the results of current trials and expand their applicability. Standardization of interventions and outcomes would allow for quantitative meta-analysis. This research should also determine whether the interventions have unintended adverse effects.

In conclusion, trials of risk assessment and behavioral interventions and counseling in pediatric clinics and early childhood home visitation programs indicated reduced abuse and neglect outcomes for children, although all trials had limitations and trials of home visitation reported inconsistent results. Clinicians are well-positioned to identify children at risk for abuse and neglect and to connect families with appropriate prevention interventions. More research is needed in key areas to provide clinicians with effective methods of doing so.
